

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

PREFACE

THIS second volume on surveying is chiefly devoted to a consideration of the various methods of conducting topographic and hydrographic surveys. While certain subjects taken up in this book might properly be included in an elementary treatise, the arrangement adopted has the decided advantage of grouping together and treating in a connected manner the different topographic and hydrographic methods.

The subject matter is divided into four parts, namely: The Control of the Survey, Filling in Topographic Details, Hydrographic Surveying and Stream Gauging, and Constructing and Finishing Maps.

In the first part some consideration has been given to Geodetic Surveying, not only to show the methods of controlling the accuracy of the survey, but also to connect the different methods taken up in Parts II and III and to show their relation to the survey as a whole. It is not the intention in any sense to present a treatise on Geodesy, but rather to discuss the subject from the standpoint of the practical surveyor. The matter is therefore limited to what any surveyor without unusual equipment might be expected to apply.

In Part II the methods of making topographic surveys are considered, including the stadia, plane-table, and photographic methods. In the chapter on The Plane Table an attempt has been made to show that this method has advantages which apparently are not appreciated by many surveyors and that its use might be much more general than it is at present. In the description of field methods a comparison has been made of the methods required for maps of different scales. In regard to

Photographic Surveying nothing has been attempted beyond an explanation of the fundamental principles involved in this method. In the chapter on the Relation of Geology to Topography, written by Professor D. W. Johnson, the subject of topography is treated from a point of view that is coming to be more and more appreciated by expert topographers. The importance of geological study to the topographer is now much emphasized by those recognized as authorities. The illustrations for this chapter were drawn by F. E. Matthes, Topographic Inspector, United States Geological Survey, to whom the authors are especially indebted.

The chapter on Hydrographic Surveying treats of the common methods of conducting harbor and river surveys. Some of the up-to-date methods have been explained in detail and are illustrated by several sets of field notes. For valuable suggestions on this subject the authors express their thanks to John R. Burke, formerly Assistant Engineer, Massachusetts Harbor and Land Commission, and to A. J. Ober, Assistant Engineer, United States Engineer Office. Chapter IX, on Stream Gauging, was written by H. K. Barrows, Engineer United States Geological Survey, who for several years has been in charge of the hydrographic work in New York and in New England. Thanks are due also to Professor W. E. Mott of the Massachusetts Institute of Technology for his criticisms of the manuscript of this chapter.

In the last two chapters the common methods of constructing and finishing topographic and hydrographic maps have been described. The details of making conventional signs have been described rather fully and some consideration has been given to the use of symbols on landscape plans. Several illustrations of topographic maps on different scales have been introduced.

The authors desire to acknowledge their indebtedness to all who have aided in the preparation of this book, especially to Professors C. Frank Allen, A. G. Robbins, C. W. Doten, and A. E. Burton of the Massachusetts Institute of Technology for criticisms and valuable suggestions.

The authors wish to express their appreciation of the excellent

PREFACE

v

The authors also desire to express their appreciation of the excellent work of W. L. Vennard, who made the drawings for illustrations.

No pains has been spared to eliminate all errors, but the authors cannot hope that their efforts in this line have been completely successful, and they will consider it a favor if their attention is called to any which may be found.

BOSTON, MASS., *September*, 1906.

PREFACE TO THE THIRD EDITION

IN this third edition the portion of Chapter V which deals with the Public Lands System and Chapter XI on Mine and Mountain Surveying have been thoroughly revised. The authors have been fortunate in securing the services of Professor William C. Hood, of the University of Kansas, in revising the articles on Public Lands Surveys. The chapter on Mine and Mountain Surveying has been rewritten by Mr. Blamey Stevens.

In order to meet the requirements of the schools in which the subject of stadia is included in the elementary course, the authors have deemed it advisable to add Appendix A, containing the fundamental principles of this method of surveying. While all of the important principles have been included in this appendix, the complete treatment of the subject, especially on the practical side, will be found in Volume II, Chapter IV.

Appendix B, which treats of the theory and use of the Planimeter, and Appendix C, in which is explained in detail the process of mounting drawing paper, appear for the first time in this edition.

**THE PRINCIPLES AND PRACTICE OF
SURVEYING.**

PART I.

USE, ADJUSTMENT, AND CARE OF INSTRUMENTS.

CHAPTER I.

GENERAL DEFINITIONS.—MEASUREMENT OF LINES.

1. **DEFINITION.**—Surveying is the art of measuring and locating lines and angles on the surface of the earth. When the survey is of such limited extent that the effect of the earth's curvature may be safely neglected it is called *Plane Surveying*. When the survey is so large that the effect of curvature of the earth must be taken into account as, for instance, in the survey of a state or a country, it is called *Geodetic Surveying*.

2. **Purposes of Surveys.**—Surveys are made for a variety of purposes such as the determination of areas, the fixing of boundary lines, and the plotting of maps. Furthermore, engineering constructions, such as waterworks, railroads, mines, bridges, and buildings, all require surveys.

3. **Horizontal Lines.**—In surveying, all measurements of lengths are **horizontal** or else are subsequently reduced to horizontal distances. As a matter of convenience, measurements are sometimes taken on slopes, but the horizontal projection is afterward computed. The distance between two points as shown on a map then is always this horizontal projection.

INSTRUMENTS FOR MEASURING LINES.

4. **THE CHAIN.**—There are two kinds of chain in common use, the *Surveyor's* (or *Gunter's*) *Chain*, and the *Engineer's Chain* (Fig. 1). Gunter's chain is 66 feet long, and its use is confined chiefly to land surveying on account of its simple relation to the acre and to the mile.

1 Gunter's Chain	= 4 Rods = 100 Links.
1 Mile	= 80 Chains.
1 Acre	= 10 Square Chains.

Evidently each link is $\frac{66}{100}$ of a foot (or 7.92 inches) long. The inch, however, is never used in surveying fieldwork.

The engineer's chain is 100 feet long and is divided into one hundred links of one foot each. Each end link is provided with a handle, the outside of which is the zero point, or end, of the chain. In these chains, every tenth link counting from either end is marked by a brass tag having one, two, three, or four points corresponding to the number of tens which it marks. The middle of the chain is marked by a round tag. In the engineer's chain then the 10-ft. and 90-ft. points, the 20-ft. and 80-ft. points, etc., are marked alike; hence it is necessary to ob-

ENGINEER'S CHAIN.

GUNTER'S HALF-CHAIN.

FIG. 1.

serve on which side of the 50-ft. point a measurement falls in order to read the distance correctly. Distances measured with the surveyor's chain are recorded as *chains and links*, (or in *chains and decimals*); while those measured with the engineer's chain are recorded as *feet and decimals*.

On account of the large number of wearing surfaces and the consequent lengthening with use, the chain should be frequently compared with a standard of length (Art. 243, p. 218). It may be adjusted to agree with the standard, by means of a nut at the

handle, which allows the length of the chain to be altered by lengthening or shortening the end link.

5. **Metric Chain.** — The *Metric Chain* is usually 20 meters long and is divided into one hundred links, each 2 decimeters long.

6. **THE TAPE.** — There are three kinds of tape in common use, — *cloth*, *metallic*, and *steel*. Cloth tapes stretch so easily that they are of little use in surveying. The so-called metallic tapes are cloth tapes having very fine brass wires woven into them to prevent stretching. They are usually graduated into feet, tenths, and half-tenths and are made in lengths of 25 ft., 50 ft., and 100 ft. When precise results are required a steel tape should be used. While a steel tape varies a slight amount in length with the temperature and with the pull, it is possible to determine the amount of these variations and hence to arrive at accurate results.

7. **Steel Tapes.** — Steel tapes may be obtained in lengths up to 500 ft., but the most common in use are the 50-ft. and 100-ft. lengths. While the shorter tapes are usually made of thin steel ribbon the longer ones are of sufficiently large cross-section to withstand hard usage. These heavy tapes are generally marked every 10 ft. by a brass tag, the 10-ft. length at one end of the tape being marked at every foot, and the last foot divided into tenths. Some of these tapes are marked every foot throughout their entire length. The light tapes are divided throughout their entire length into feet, tenths, and hundredths, each line being etched on the steel. The numbering is continuous from 0 ft. to 100 ft. These tapes are more convenient to handle than the heavy ones, but are not suited to very rough work as they are easily kinked and broken. They can be readily mended, however, by riveting to the back of the tape a piece of tape of the same width.

Since the surveyor's measurements are usually in feet and decimals, they are not in convenient form for use by mechanics in construction work. It is therefore often necessary to convert decimals of a foot into inches and *vice versa*. The following table shows the general relation between these two and is sufficiently close for most work

TABLE 1.
DECIMALS OF FOOT IN INCHES.

DECIMAL OF FOOT.		INCHES.
.01	=	$\frac{1}{8}$ —
.08	=	1 —
.17	=	2 +
.25	=	3 (exact)
.50	=	6 (exact)
.75	=	9 (exact)

Decimals of a foot can easily be converted mentally into inches, by use of the equivalents in the above table, for example, 0.22 ft. = .25 — .03 = 3" — $\frac{3}{8}$ " = 2 $\frac{3}{8}$ ".

In surveying farms, timber lands, or other property of low value, chain measurements are usually of sufficient accuracy and the chain is well adapted to work in rough country. In city surveys, and in fact in all surveys where great accuracy is demanded, the steel tape is indispensable. In preliminary railroad surveys the engineer's chain, which formerly was used exclusively, is gradually being replaced by the long heavy tape which, while adapted to rough work, will at the same time give accurate results.

8. THE STADIA. — Where it is desired to measure distances with great rapidity but not with very great accuracy the *stadia* method is coming to be very generally used. The distance is obtained by simply sighting with a transit instrument at a graduated rod held at the other end of the line and noting the space on the rod included between two special cross-hairs set in the instrument at a known distance apart. From this observed interval on the rod the distance from the transit to the rod can be easily calculated. (See Appendix A, p. 517.)

9. OTHER INSTRUMENTS. — *Wooden Rods* are used in certain kinds of work for making short measurements, usually less than 15 ft.

The *Two-Foot Rule* divided into tenths and hundredths of a foot is very convenient for short measurements.

The *Odometer* is an instrument which may be attached to a carriage in such a manner as to register the number of revolutions of one of the wheels. The circumference of the wheel being known the approximate distance traversed is easily determined.

MEASUREMENT OF LINES.**10. MEASUREMENT OF A HORIZONTAL LINE WITH A CHAIN.**

— This work is done by two chainmen using a chain and a set of eleven steel marking pins. One man, called the head-chainman, carries ten of the marking pins and the front end of the chain. The rear-chainman takes the eleventh pin and the other end of the chain. The head-chainman then goes forward keeping as nearly on the line as he can. The rear-chainman holds his end of the chain just to one side of the initial point, as in Fig. 2, so that any jerking of the chain will not disturb the pin at which he is holding. The rear-chainman, with his eye over the point, places the head-chainman in line with some object, such as a

HEAD-CHAINMAN.

REAR-CHAINMAN.

FIG. 2. MEASURING A HORIZONTAL LINE WITH A CHAIN.

sighting-rod, which marks the other end or some point on the line. When the head-chainman is nearly in line he takes a pin and, standing to one side of the line, holds it upright on the ground a foot or so short of the end of the chain and the rear-chainman motions him to the right or left until his pin is on the line. When the head-chainman has the pin in line he stretches the chain taut, seeing that there are no "kinks" and that no obstructions cause bends in the chain. The rear-chainman at the same time holds his end of the chain at his pin and when he calls out, "All right here," the head-chainman stretching the

chain past his line pin, removes this line pin, places it at the end of the chain, as in Fig. 2, and presses it vertically into the ground. When the chainmen are experienced the pin may be set for both line and distance at the same time. When the pin is in place the head-chainman calls, "All right," the rear-chainman takes the pin left at his end of the line and they proceed to the next chain-length. The pin that the rear-chainman has is a record of the first chain-length. Just before reaching the second pin the rear-chainman calls out, "Chain," to give the head-chainman warning that he has nearly reached a chain-length. The process of lining in the head-chainman and measuring a chain-length is then repeated. When the third pin is stuck in the ground the rear-chainman pulls the second pin; in this way the number of pins the rear-chainman holds is a record of the number of chain-lengths measured. There is always one pin in the ground which simply marks the distance and is not counted.

When 10 chains have been measured the head-chainman will be out of pins and calls to the rear-chainman, who brings forward 10 pins. The pins are then counted by **both chainmen**. Every time 10 chains are measured a record of it is made in note-books kept by **both men** and the process is repeated until the end of the line is reached.

In measuring the fraction of a chain the head-chainman holds his end of the chain at the required point and the fractional distance is read by the rear-chainman at the last pin. In some kinds of work, however, it is more convenient to draw the chain ahead past the end point and, while the rear-chainman holds his end of the chain at the last pin, the head-chainman reads the fractional measurement. The links are read by counting from the proper tag and the tenths of a link are estimated. Great care should be taken to count the tags from the proper end of the chain since the 10-ft. points each side of the center, as has been explained, are marked alike.

It can be easily shown that if a pin is placed a few tenths of a foot to the right or left of the line the resulting error in the **distance** is very small and consequently "lining in" by eye is accurate enough, so far as the **distance** is concerned. But when

any side measurements or angles are to be taken the points should be set accurately on line by means of a transit instrument.

The chain should always be kept stretched out full length; it should never be doubled back on itself as it may become tangled and the links bent.

Much time can be saved if the head-chainman will pace the chain-length and then place himself very nearly in the line by means of objects which he knows to be on line as, for example, the instrument, a pole, or the last pin. The beginner should pace, several times, some line of known length so as to determine approximately how many steps he takes in 100 ft. In doing this he should take his natural step and avoid any attempt to take steps just 3 ft. long.

11. Measurement of a Horizontal Line with a Chain on Sloping Ground.—If the measurement is not on level ground the chain must be held horizontal and the distance transferred to the ground by means of a plumb-line. This is difficult to do accurately and is a fruitful source of error. Beginners usually hold the downhill end of the chain too low. Horizontal lines on buildings are very useful in judging when the chain is level. Since it is supported only at the ends its weight will cause it to sag so that the distance between the ends is less than a chain-length. The pull exerted on the chain should be such that it will stretch enough to balance as nearly as possible the shortening due to sag.

Whenever a slope is so steep that the chainman on the lower end cannot plumb high enough to keep the chain horizontal the measurement must be made in sections, 50-ft., 20-ft., or even 10-ft. lengths being used. Mistakes will be avoided if the rear-chainman comes forward at each measurement and holds the same fractional point on the chain that the head-chainman held, and so on until a whole chain-length has been measured. In this way it will be unnecessary to count the fractional distances, but care should be taken that these pins which marked the intermediate points are returned to the head-chainman so that the count of the chain-lengths will not be lost. Chaining downhill will, in general, give more accurate results than chaining uphill, because in the former case the rear end is held firmly at a point

on the ground so that the head-chainman can pull steadily on the chain and transfer the distance to the ground by means of the plumb-line; in the latter case the rear-chainman is plumbing his end of the chain over the point and it is difficult to hold it steady. The result is that the head-chainman cannot easily judge where the pin should be placed.

12. MEASUREMENT WITH A STEEL TAPE. — In measuring with the steel tape the process is similar to that described for the chain. As the tape is used for more precise work than the chain it is necessary to employ more exact methods of marking the intermediate points. In some cases stakes are driven into the ground and tacks or pencil marks used to mark the points. A small nail pressed into the ground so that the center of the head is in the proper position makes a good temporary mark, but of course is easily lost. In measuring on the surfaces of hard roads, spikes are used for permanent marks.

Measurements of important lines which are not checked by some geometric test should be checked by repeating the measurement, and in such a way as not to use the same intermediate points taken in the first measurement.*

Where distances are to be measured continuously from the initial point of a line without regard to angles in the line, as in railroad surveys, it is customary to establish the 100-ft. points. Mistakes will often be avoided by setting the 100-ft. points as follows: — suppose an angle to occur at 870.1 ft. from the point of beginning; this would be called "Station 8 + 70.1." To set "Station 9" the 70.1-ft. point of the tape should be held on stake 8 + 70.1 and the stake at station 9 placed at the 100-ft. point of the tape. This is preferable to making a measurement of 29.9 ft. from the zero end of the tape.

* In measuring with the tape some prefer to make a series of measurements between points set in the ground a little less than 100 ft. apart, summing up the partial measurements when the end of the line is reached. This guards against the mistake of omitting a whole tape-length. Another advantage is that it is easier to read the distance to a fixed point than to set a point accurately at the end of the tape; this is especially true in measurements where plumbing is necessary. This method takes less time than the usual method, but it is not applicable when it is necessary to mark the 100-ft. points on the line.

13. COMMON SOURCES OF ERROR IN MEASUREMENT OF LINES. —

1. Not pulling chain or tape taut.
2. Careless plumbing.
3. Incorrect alignment.
4. Effect of wind.
5. Variation in temperature.
6. Erroneous length of chain or tape.

14. COMMON MISTAKES IN READING AND RECORDING MEASUREMENTS. —

1. Failure to observe the position of the zero point of the tape.
(In some tapes it is not at the end of the ring.)
2. Omitting a whole chain-or tape-length.
3. Reading from wrong end of chain, as 40 ft. for 60 ft., or in the wrong direction from a tag, as 47 ft. for 53 ft.
4. Transposing figures, e.g., 46.24 for 46.42 (mental); or reading tape upside down, e.g., 6 for 9, or 86 for 98.
5. Reading wrong foot-mark, as 48.92 for 47.92.

15. AVOIDING MISTAKES. — Mistakes in counting the tape-lengths may be avoided if more than one person keeps the tally. Mistakes of reading the wrong foot-mark may be avoided by noting not only the foot-mark preceding, but also the next following foot-mark, as, "46.84 . . . 47 feet," and also by holding the tape so that the numbers are right side up when being read.

In calling off distances to the note keeper, the chainman should be systematic and always call them distinctly and in such terms that they cannot be mistaken. As an instance of how mistakes of this kind occur, suppose a chainman calls, "Forty-nine, three;" it can easily be mistaken for "Forty-nine feet." The note keeper should repeat the distances aloud so that the chainman may know that they were correctly understood. It is frequently useful in doubtful cases for the note keeper to use different words in answering, which will remove possible ambiguity. For example, if the chainman calls, "Thirty-six, five," the note keeper might answer, "Thirty-six and a half." If the

chainman had meant 36.05 the mistake would be noticed. The chainman should have called in such a case, "Thirty-six naught five." The following is a set of readings which will be easily misinterpreted unless extreme care is taken in calling them off.

40.7 — "Forty and seven."

47.0 — "Forty seven naught."

40.07 — "Forty, — naught seven."

All of these might be carelessly called off, "Forty-seven."

In all cases the chainmen should make **mental estimates** of the distances when measuring, in order to avoid large and absurd mistakes.

16. ACCURACY REQUIRED. — If, in a survey, it is allowable to make an error of one foot in every five hundred feet the chain is sufficiently accurate for the work. To reach an accuracy of 1 in 1000 or greater with a chain it is necessary to give careful attention to the **pull**, the **plumbing**, and the deviation from the **standard length**. With the steel tape an accuracy of 1 in 5000 can be obtained without difficulty if ordinary care is used in plumbing and aligning, and if an allowance is made for any considerable error in the length of the tape. For accuracy greater than about 1 in 10,000 it is necessary to know definitely the temperature and the tension at which the tape is of standard length and to make allowance for any considerable variation from these values. While the actual deviation from the U. S. Standard under ordinary conditions may be 1 in 10,000, still a series of measurements of a line taken under similar conditions may check **themselves** with far greater precision.

17. AMOUNT OF DIFFERENT ERRORS. — The surveyor should have a clear idea of the effects of the different errors on his results. For very precise work they should be accurately determined, but for ordinary work it is sufficient to know approximately the amount of each of them. A general idea of the effect of these errors will be shown by the following.

18. Pull. — At the tension ordinarily used, the light steel tape will stretch between 0.01 and 0.02 ft. in 100 ft. if the pull is increased 10 pounds.

19. Temperature. — The average coefficient of expansion for a steel tape is nearly 0.0000063 for 1° F. Hence a change of temperature of 15° produces nearly 0.01 ft. change in the length of the tape. Tapes are usually manufactured to be of standard length at 62° F., with a pull of 12 lbs. on them while supported throughout their entire length.

20. Alignment. — The error in length due to poor alignment can be calculated from the approximate formula

$$c - a = \frac{h^2}{2c} *$$

where h is the distance of the end of the tape from the line, c is the length of the tape, and a is the distance along the straight line. For example, if one end of a 100-ft. tape is held 1 ft. to one side of the line the error produced in the length of the line will be $\frac{1^2}{2 \times 100} = 0.005$ ft., (about $\frac{1}{16}$ inch). The correction to be applied to the distance when the two ends of the tape are not at the same level is computed in the same way.

21. Sag. — If a tape is suspended only at the ends it will hang in a curve which is known as the "catenary." On account of this curvature the distance between the end points is evidently less than the length of the tape. The amount of this shortening, called the *effect of sag*, depends upon the weight of the tape, the distance between the points of suspension, and the pull exerted

* In the right triangle,

$$c^2 - a^2 = h^2,$$

$$(c + a)(c - a) = h^2,$$

assuming $c = a$ and applying it to the first parenthesis only,

$$2c(c - a) = h^2 \text{ (approximately)}$$

$$c - a = \frac{h^2}{2c} \text{ (approximately)}$$

Similarly $c - a = \frac{h^2}{2a} \text{ (approximately)}$

It is evident that the smaller h is in comparison with the other two sides the more exact will be the results obtained by this formula. This formula is even correct to the nearest $\frac{1}{16}$ ft. when $h = 14$ ft. and $a = 100$ ft., or when $h = 30$ ft. and $a = 300$ ft.

at the ends of the tape. With a 12-lb. pull on an ordinary 100-ft. steel tape supported at the ends the effect of sag is from .005 ft. to .01 ft.

22. Effect of Wearing on Length of the Chain. — When a chain is new it is very nearly the standard length. During its first use the links become bent and the chain thus shortened. But there are nearly six hundred wearing surfaces and before long the small amount of wear on each surface lengthens the chain an appreciable amount. It is very common to find chains which, after considerable use, have lengthened 0.3 ft. or more.

23. ACCURACY OF MEASUREMENTS. — In surveying we are dealing entirely with measurements. Since absolute accuracy can never be attained, we are forced to make a careful study of the **errors** of measurement. Extremely accurate measurements are expensive, and the cost of making the survey usually limits its accuracy. On the other hand, if a given degree of accuracy is required, the surveyor must endeavor to do the work at a minimum cost. In most surveys certain measurements are far more important than others and should therefore be taken with more care than the relatively unimportant measurements.

The surveyor should distinguish carefully between errors which are of such a nature that they tend to balance each other and those which continually accumulate. The latter are by far the more serious. Suppose that a line 5000 ft. long is measured with a steel tape which is 0.01 ft. too long and that the error in measuring a tape-length is, say, 0.02 ft., which may of course be a + or a - error. There will then be 50 tape-lengths in the 5000-ft. line. A study of the laws governing the distribution of accidental errors (Method of Least Squares) shows that in such a case as this the number of errors that will probably remain uncompensated is the **square root of the total number of opportunities for error**, i.e., in the long run this would be true. Hence the total number of such uncompensated errors in the line is 7; and $7 \times 0.02 = 0.14$ ft., which is the total error due to inaccuracy in marking the tape-lengths on the ground. Since the error due to erroneous length of tape increases directly as the number of measurements, and since these errors are not compensating, the total error in the line due to the fact that the tape is 0.01 ft. too

long is $50 \times 0.01 = 0.50$ ft. The small (0.01) **accumulative error** is therefore seen to have far greater effect than the larger (0.02) **compensating error**. ✓

PROBLEMS.

1. A distance is measured with an engineer's chain and found to be 796.4 ft. The chain when compared with a standard is found to be 0.27 ft. too long. What is the actual length of the line?

2. A metallic tape which was originally 50 ft. is found to be 50.14 ft. long. A house 26 ft. \times 30 ft. is to be laid out. What measurements must be made, using this tape, in order that the house shall have the desired dimensions?

3. A steel tape is known to be 100.000 ft. long at 62° F. with a pull of 12 lbs. and supported its entire length. Its coefficient of expansion is 0.0000063 for 1° F. A line was measured and found to be 142.67 ft. when the temperature was 8° below zero. What is the true length of the line?

4. In chaining down a hill with a surveyor's chain the head-chainman held his end of the chain 1.5 ft. too low. What error per chain-length would this produce?

5. In measuring a line with a 100-ft. tape the forward end is held 3 ft. to the side of the line. What is the error in one tape-length?

CHAPTER II.

MEASUREMENT OF DIRECTION.

24. THE SURVEYOR'S COMPASS.—The surveyor's compass (Fig. 3) is an instrument for determining the direction of a line with reference to the direction of a magnetic needle. The needle is balanced at its center on a *pivot* so that it swings freely in a horizontal plane. The pivot is at the center of a horizontal circle which is graduated to degrees and half-degrees, and numbered from two opposite zero points each way to 90° . The zero points are marked with the letters N and S, and the 90° points are marked E and W. The circle is covered with a glass plate to protect the needle and the graduations, the part enclosed being known as the *compass-box*. A screw is provided for raising the needle from the pivot by means of a lever. The needle should always be raised when the compass is lifted or carried, to prevent dulling the pivot-point; a dull pivot-point is a fruitful source of error. Both the circle and the pivot are secured to a brass frame, on which are two vertical sights so placed that the plane through them also passes through the two zero points of the circle. This frame rests on a tripod and is fastened to it by means of a ball-and-socket joint. On the frame are two spirit levels at right angles to each other, which afford a means of leveling the instrument. This ball-and-socket joint is connected with the frame by means of a spindle which allows the compass-head to be revolved in a horizontal plane, and to be clamped in any position.

The magnetic needle possesses the property of pointing in a fixed direction, namely, the *Magnetic Meridian*. The horizontal angle between the direction of this meridian and of any other line may be determined by means of the graduated circle, and this angle is called the *Magnetic Bearing* of the line, or simply its *Bearing*. By means of two such bearings the angle between two lines may be obtained. Bearings are reckoned from 0° to 90° ,

the 0° being either at the N or the S point and the 90° either at the E or the W point. The quadrant in which a bearing falls is designated by the letters N.E., S.E., S.W., or N.W. For example, if a line makes an angle of 20° with the meridian and is in the southeast quadrant its bearing is written S 20° E. Sometimes the bearing is reckoned in a similar manner from

FIG. 3. SURVEYOR'S COMPASS.

the geographical meridian, when it is called the *true bearing*. In general this will not be the same as the magnetic bearing. True bearings are often called *azimuths*, and are commonly reckoned from the **south** point right-handed (clockwise) to 360° ; i.e., a line running due West has an azimuth of 90° , a line due North an azimuth of 180° . Sometimes, however, the azimuth

is reckoned from the **north** as in the case of the azimuth of the Pole-Star (Art. 206, p. 180).

25. THE POCKET COMPASS. — The *pocket compass* is a small hand instrument for obtaining roughly the bearing of a line. There are two kinds, the *plain* and the *prismatic*. The former is much like the surveyor's compass, except that it has no sights. In the prismatic compass the graduations, instead of being on the compass-box, are on a card which is fastened to the needle (like a mariner's compass) and which moves with it. This compass is provided with two short sights and the bearing can be read, by means of a prism, at the same instant that the compass is sighted along the line.

26. METHOD OF TAKING A MAGNETIC BEARING. — The surveyor's compass is set up (and leveled) at some point on the line whose bearing is desired. The needle is let down on the pivot; and the compass is turned so that the sights point along the line. While looking through the two sights the sur-

FIG. 4. DIAGRAM ILLUSTRATING READING OF BEARINGS.

veyor turns the compass-box so that they point exactly at a lining pole or other object marking a point on the line. The glass should be tapped lightly over the end of the needle to be sure that the latter is free to move. If it appears to cling to the glass this may be due to the glass being electrified, which condition can be removed at once by placing the moistened finger on the glass. The position of the end of the needle is then read on the circle and recorded. Bearings are usually read to the nearest quarter of a degree.

Since the needle stands still and the box turns under it, the letters **E** and **W** on the box are reversed from their natural position so that the reading of the needle will not only give the

angle but also the proper quadrant. Reference to Fig. 4 will show the following rule to be correct : — **When the north point of the compass-box is toward the point whose bearing is desired, read the north end of the needle.** When the south point of the box is toward the point, read the south end of the needle. If a bearing of the line is taken looking in the opposite direction it is called the *reverse bearing*.

Since iron or steel near the instrument affects the position of the needle, great care should be taken that the chain, axe, or marking pins are not left near the compass. Small pieces of iron on the person, such as keys, iron buttons, or the iron wire in a stiff hat, also produce a noticeable effect on the needle. Electric currents are a great source of disturbance to the needle and in cities, where electricity is so common, the compass is practically useless.

In reading the compass-needle, the surveyor should take care to read the farther end of the needle, always looking *along* the needle, not across it. By looking at the needle sidewise it is possible to make it **appear** to coincide with a graduation which is really at one side of it. This error is called *parallax*.

27. THE EARTH'S MAGNETISM. — Dip of the Needle. — The earth is a great magnet. On account of its magnetic influence a permanent magnet, such as a compass-needle, when freely suspended will take a definite direction depending upon the direction of the lines of magnetic force at any given **place** and **time**. If the needle is perfectly balanced before it is magnetized it will, after being magnetized, dip toward the pole. In the northern hemisphere the end of the needle toward the north pole points downward, the inclination to the horizon being slight in low latitudes and great near the polar region. In order to counteract this dipping a small weight, usually a fine brass wire, is placed on the higher end of the needle at such a point that the needle assumes a horizontal position.

28. DECLINATION OF THE NEEDLE. — The direction which the needle assumes after the counterweight is in position is called the magnetic meridian and rarely coincides with the true meridian. The angle which the needle makes with the true meridian is called the *declination of the needle*. When the north

end of the needle points east of the true, or geographical, north the declination is called *east*; when the north end of the needle points west of true north it has a *west* declination.

29. Variations in Declination. — The needle does not constantly point in the same direction. Changes in the value of the declination are called *variations of the declination*.* The principal variations are known as the *Secular, Daily, Annual, and Irregular*.

The *Secular Variation* is a long, extremely slow swing. It is probably periodic in character but its period covers so many years that the nature of it is not thoroughly understood. The following table shows the amount of secular variation as observed in Massachusetts during two centuries.

TABLE 2.

OBSERVED DECLINATIONS OF NEEDLE IN EASTERN MASSACHUSETTS.†

YEAR.	DECLINATION.
1700	10° 31' W.
1750	7° 13' W.
1800	6° 28' W.
1850	9° 10' W.
1900	12° 00' W.

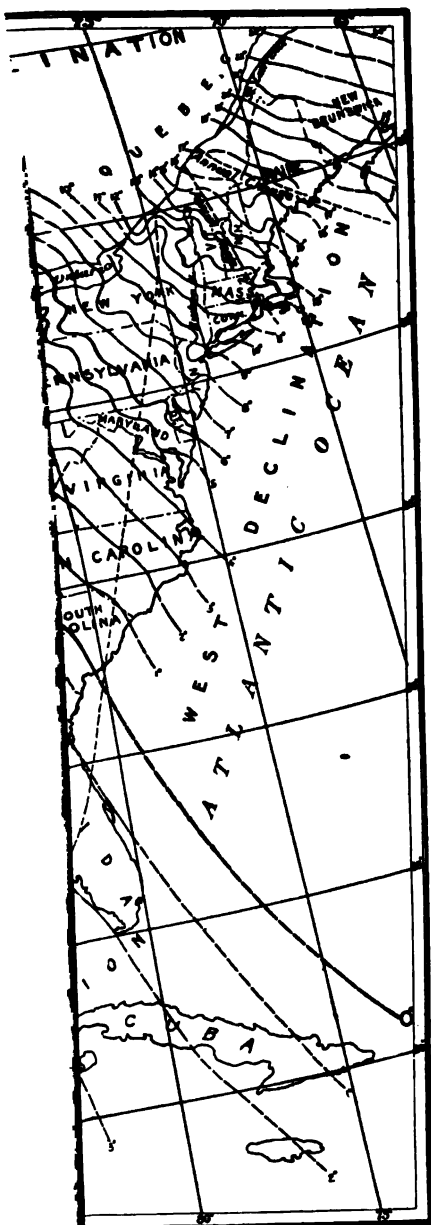

In the United States all east declinations are now gradually decreasing and all west declinations are gradually increasing, at an average rate of about 2 minutes per year.

The *Daily Variation* consists of a swing which averages about 7 minutes of arc from its extreme easterly position at about 8 A.M. to its most westerly position at about 1.30 P.M. It is in its mean position at about 10 A.M. and at 5 or 6 P.M. The amount of daily variation is from 3 to 12 minutes according to the season and the locality.

The *Annual Variation* is a periodic variation so small (about one minute a year) that it need not be considered in surveying work.

* The angle called *Declination* by surveyors is usually called *Variation* by navigators.

† See p. 107 of U. S. Coast and Geodetic Survey special publication entitled "U. S. Magnetic Declination Tables and Isogonic Chart for 1902, and Principal Facts Relating to the Earth's Magnetism," by L. A. Bauer, issued in 1902.

Irregular Variations in the declination are due chiefly to magnetic storms. They are uncertain in character and cannot be predicted. They are, however, usually observed whenever there is a display of the Aurora Borealis. Such storms often cause variations of from ten to twenty minutes in the United States and even more in higher latitudes.

30. Isogonic Chart.—If lines are drawn on a map so as to join all places where the declination of the needle is the same at a given time, the result will be what is called an *isogonic chart*. (See Fig. 5.) Such charts have been constructed by the United States Coast and Geodetic Survey. While they do not give results at any place with great precision they are very useful in finding approximate values of the declination in different localities.

An examination of the isogonic chart of the United States shows that in the Eastern States the needle points west of north while in the Western States it points east of north. The line of no declination, or the *agonic line*, passes at the present time (1906) through the Carolinas, Ohio and Michigan.

31. OBSERVATIONS FOR DECLINATION.—For any survey where the value of the present declination is important, it should be found by special observations. The value found at one place may be considerably different from that of a place only a few miles distant. The method of finding the declination by observation on the Pole-Star (Polaris) is described in Art. 210, p. 187.

ADJUSTMENTS OF THE COMPASS.

32. The three adjustments which need to be most frequently made are (1) adjusting the bubbles, (2) straightening the needle, (3) centering the pivot-point.

33. ADJUSTMENT OF THE BUBBLES.—To make the Plane of the Bubbles Perpendicular to the Vertical Axis.—Level the instrument in any position. Turn 180° about the vertical axis and, if the bubbles move from the center, bring each half-way back by means of the adjusting screws; and repeat the process until the desired fineness of adjustment is secured.

34. DETECTING ERRORS IN ADJUSTMENT OF THE NEEDLE.
—If the readings of the two ends of the needle are not 180°

apart, this may be due to the needle being bent, to the pivot-point not being in the center of the graduated circle, or to both. If the difference of the two readings is the same in whatever direction the compass is turned, it follows that the needle is bent but the pivot-point is in the center of the circle. (See Fig. 6.) The bent needle is represented by the line AOB and the position of a straight needle shown by the line AOC . In the two positions shown it is seen that the difference in readings will be the same, i.e., arc $CB = \text{arc } C'B'$. If the difference of the readings varies as the compass is turned around it follows that the

FIG. 6. BENT COMPASS-NEEDLE.

pivot-point is not in the center, and the needle may or may not be bent. Suppose the needle is straight but the pivot is not in the center, then the effect in different parts of the circle is shown in Fig. 7. When the needle is in the position AD , perpendicular to CC' , (where C is the true center and C' is the position of the pivot-point), then the error is a maximum. If B is a point 180° from A then the difference of the two readings is BD . When the needle is at $A'D'$ the error is less than before and equals $B'D'$. When the needle is in the line CC' , i.e., in the position $A''D''$, the ends read alike.

FIG. 7. PIVOT-POINT OUT OF CENTER.

In making these adjustments it is better to first straighten the needle, because the error due to the needle being bent can be detected independently of the error of the pivot.

35. TO STRAIGHTEN THE COMPASS-NEEDLE.—Level the instrument and let the needle down on the pivot. Remove the glass cover. By means of a brass wire or a light stick of wood

steady the needle so that one end of it, say the south end, is opposite some graduation on the circle as *A* in Fig. 8. Note the position of the north end of the needle *C*. Now, without moving the compass itself, turn the needle around so that the north end is at the graduation *A*. Hold it in this position with the brass wire and read the position of the south end *C'*. One-half the difference of the readings, or, the distance *C'D* is the

FIG. 8. STRAIGHTENING THE COMPASS-NEEDLE.

amount by which the needle is bent. Carefully remove the needle from the pivot and bend it by the amount *C'D* in the direction which will move the south end half-way back from *C'* toward *C*. It is better not to touch the needle with the hands more than is absolutely necessary as this weakens the magnetism. Instrument makers usually leave the central part of the needle quite soft so that it can be easily bent in making this adjustment.

Since the amount by which the needle is bent is a matter of estimation it should be replaced on the pivot and the test repeated until it is found that reversing the needle does not change the readings.

36. TO CENTER THE PIVOT-POINT. — If the difference of readings of the two ends of the needle varies in different parts of the circle it is due to the pivot-point being out of center. Take readings of the two ends of the needle in various positions of the compass and find the position of the needle in which the difference of the two readings is greatest (Art. 34, p. 25). The pivot is to be bent at right angles to this direction an amount equal to half this difference. Remove the needle and bend the pivot by means of a pair of small flat pliers. Replace the needle and see if the difference of end readings is zero. If not, the pivot must be bent until this condition is fulfilled. As the pivot may become bent somewhat in a direction other than that intended, a complete test for adjustment must be made again, and the process continued until the difference in the readings of the ends of the needle is zero in all positions of the compass. The

metal at the base of the pivot is left soft so that it can be easily bent.

37. TO REMAGNETIZE THE NEEDLE. — Rub each end of the needle from the center toward the end several times with a bar-magnet, using the N end of the magnet for the S end of the needle and *vice versa*. (The N end of the magnet attracts the S end of the needle and repels its N end.) When the magnet is drawn along the needle it should move in a **straight line**, parallel to the axis of the needle. When returning the bar from the end of the needle toward the center, lift it several inches **above** the needle as indicated in Fig. 9.

FIG. 9. REMAGNETIZING THE COMPASS-NEEDLE.

38. COMMON SOURCES OF ERROR IN COMPASS WORK. —

1. Iron or steel near compass.
2. Parallax in reading needle.

39. COMMON MISTAKES. —

1. Reading wrong end of needle.
2. Not letting needle down on pivot.
3. Reading the wrong side of the 10th degree, viz., reading 61° instead of 59° .

40. DETECTING LOCAL ATTRACTION OF THE NEEDLE.—As the needle is always affected by masses of iron near the compass it is important that the bearings in any survey should be checked. This is most readily done by taking the bearing of any line from both its ends or from intermediate points on the line. If the two bearings agree it is probable that there is no local magnetic disturbance. If the two do not agree it remains to discover which is correct.

In Fig. 10 suppose that the compass is at *A* and that the

FIG. 10. DIAGRAM ILLUSTRATING LOCAL ATTRACTION AT *A*.

bearing of *AB* is $N\ 50^{\circ}\frac{1}{4}\ E$, and with the compass at *B* the bearing *BA* is found to be $S\ 49^{\circ}\ W$. It is evident that there is local attraction at one or both points. In order to ascertain the correct magnetic bearing, turn the compass toward a point *C* which is apparently free from magnetic disturbance, and observe the bearing of *BC*, which is, say, $S\ 72^{\circ}\ E$. Now move the compass to *C* and observe the bearing *CB*. If this is $N\ 72^{\circ}\ W$ it indicates that there is no local attraction at *C* or *B*, hence $S\ 49^{\circ}\ W$ is the correct bearing of line *BA*, and there is $1^{\circ}\frac{1}{4}$ error in all bearings taken at *A*. If the bearings of *BC* and *CB* had not agreed it would have been necessary to take the bearing and reverse bearing of a new line *CD*. This process is continued until a line is found whose bearing and reverse bearing differ by exactly 180° .

41. CALCULATING ANGLES FROM BEARINGS.—In calculating the angle between two lines it is necessary only to remember that the bearing is in all cases reckoned from the meridian, either N or S, toward the E and W points. In Fig. 11,

AOB = difference of bearings.

AOC = 180° — sum of bearings.

AOD = 180° — difference of bearings.

AOF = sum of bearings.

FIG. 11.

PROBLEMS.

1. Compute the angle AOB from the given bearings in each of the following cases.

(a) OA , $N\ 39^\circ\frac{1}{2}\ E.$

OB , $N\ 76^\circ\frac{1}{2}\ E.$

(b) OA , $N\ 35^\circ\ 15'\ E.$

OB , $S\ 88^\circ\ 00'\ W.$

(c) OA , $N\ 15^\circ\ E.$

OB , $S\ 36^\circ\ E.$

(d) OA , $N\ 40^\circ\ 15'\ E.$

OB , $N\ 66^\circ\ 45'\ W.$

2. The bearing of one side of a field in the shape of a regular hexagon is $S\ 10^\circ\frac{1}{2}\ E.$ Find the bearings of the other sides taken around the field in order.

3. (a) In 1859 a certain line had a bearing of $N\ 21^\circ\ W.$ The declination of the needle at that place in 1859 was $8^\circ\ 39'\ W.$ In 1902 the declination was $10^\circ\ 58'\ W.$ What was the bearing of the line in 1902?

(b) In 1877 a line had a bearing of $N\ 89^\circ\ 30'\ E.$ The declination was $0^\circ\ 13'\ E.$ In 1902 the declination was $1^\circ\ 39'\ W.$ Find the bearing of the line in 1902.

(c) At a certain place the declination was $4^\circ\ 25'\ W$ in 1700, $1^\circ\ 39'\ W$ in 1750, $0^\circ\ 21'\ E$ in 1800, $1^\circ\ 03'\ W$ in 1850, $4^\circ\ 00'\ W$ in 1900. If a line had a bearing of $S\ 65^\circ\frac{1}{2}\ W$ in 1900, what was its bearing in 1700, 1750, 1800, and 1850?

4. The following bearings were observed with a compass: AB , $N\ 27^\circ\frac{1}{2}\ E.$; BA , $S\ 25^\circ\frac{1}{2}\ W.$; BC , $S\ 88^\circ\ W.$; CB , $N\ 87^\circ\frac{1}{2}\ E.$; CD , $N\ 47^\circ\frac{1}{2}\ W.$; DC , $S\ 47^\circ\frac{1}{2}\ E.$ Find the true bearing of $AB.$ Where is the local attraction? Which way is the needle deflected at each point, and how much?

CHAPTER III.

MEASUREMENT OF ANGLES.

THE TRANSIT.

42. **GENERAL DESCRIPTION OF THE TRANSIT.** — The engineer's transit is an instrument for measuring horizontal and vertical angles. A section of the transit is shown in Fig. 12.

FIG. 12. SECTION OF TRANSIT.

A, inner spindle; *B*, outer spindle; *C*, upper plate; *D*, lower plate; *E*, graduated circle; *F*, vernier; *G*, magnetic needle; *H*, upper clamp (turned 90° from its normal position so as to show in section, corresponding tangent screw not shown); *J*, lower clamp; *K*, lower tangent screw; *L*, leveling screws; *M*, ball-and-socket joint; *N*, shifting head; *O*, base of transit.

Two spindles, one inside the other, are each attached to a horizontal circular plate, the outer spindle being attached to the lower plate and the inner one to the upper plate. Except in some older instruments, the lower plate carries a graduated circle and the upper plate carries the *verniers* for reading the circle. On this upper plate are two uprights or *standards*

supporting a horizontal axis. The length of the telescope and the height of the standards are commonly such as to allow the telescope to make a complete rotation on its horizontal axis. The motion of this axis is usually controlled by a clamp and a *slow-motion screw* called a *tangent screw*. In older instruments this often consisted of two opposing screws; in modern instruments it usually consists of a single screw with an opposing spring. At the center of the horizontal axis is a telescope attached at right angles to it.

For leveling the instrument, there are two spirit levels on the upper plate, one parallel and the other at right angles to the horizontal axis. The spirit level which is parallel to the axis is the more important one because it controls the position of the horizontal axis of the telescope; it should be and generally is made more sensitive than the other. In the transit, the leveling is done by means of four (sometimes three) leveling screws.

The upper plate is usually provided with a magnetic needle and a graduated circle so that the transit may be used as a compass. The lower spindle is attached to the base of the instrument by means of a ball-and-socket joint the same as in the compass. Both the upper and lower plates are provided with clamps for holding them in any desired position and with tangent screws for making exact settings.

At the center of the ball-and-socket joint is a ring to which the plumb-line may be attached. The plumb-bob used with the transit is generally heavier than that used in taking tape measurements. Modern transits are so made that the entire head of the instrument can be shifted laterally with reference to the tripod and can thus be readily placed exactly over a point on the ground.

The horizontal circle is usually graduated either to half-degrees or to 20-minute spaces. The graduations are often numbered from 0° to 360° by two rows of figures running in opposite directions. In some transits they are numbered from 0° to 360° in a right-hand direction and, by a second row of figures, from 0° each way to 180° ; and still others (older types) are numbered from 0° to 90° in opposite directions, like a compass circle. Transits are all provided with two opposite verniers.

FIG. 13. ENGINEER'S TRANSIT.

FIG. 14. LONGITUDINAL SECTION OF A TRANSIT TELESCOPE.

43. The *normal* or *direct* position of the transit is with the upper clamp and its tangent screw nearest the observer and the focusing screw of the telescope on the right-hand side (in some instruments, on top) of the telescope. When the instrument is turned 180° in azimuth from the direct position and the telescope is *inverted* (turned over about the horizontal axis) it is said to be in the *reversed* position.

44. If the telescope is provided with a long level tube and a vertical circle, or arc, it is called an *Engineer's Transit*, or *Surveyor's Transit*. (Fig. 13.) If it does not have these attachments it is called a *Plain Transit*.

45. **THE TELESCOPE.** — The essential parts of the telescope are the *objective*, the *cross-hairs*, and the *eyepiece*. (See Fig. 14.)

The line of sight, or *line of collimation*, is the straight line drawn through the optical center of the objective and the point of intersection of the cross-hairs. When light from any point *A* falls on the objective, the rays from *A* are bent and brought to a focus at a single point *B* called the *image*. The only exception to this is in the case when *A* is on the optical axis; the ray which coincides with the optical axis is not bent. The cross-hairs are placed in the telescope tube near where the image is formed, as shown in Fig. 14. The objective is screwed into a tube, which is inside the main tube and which can be moved by means of a rack-and-pinion screw so as to bring the plane of the image of the object into coincidence with the plane of the cross-hairs. The instrument is so constructed that the motion

of this tube is **parallel** to the line of sight. The eyepiece is simply a microscope for viewing the image and the cross-hairs. When the plane of the image coincides with the plane of the cross-hairs, both can be viewed at the same instant by means of the eyepiece. The adjustment of the eyepiece and the objective, to enable the cross-hairs and the image to be clearly seen at the same time, is called *focusing*.

In focusing, first the eye-piece tube is moved in or out until the cross-hairs appear distinct; then the objective is moved until the image is distinct. If it is found that the cross-hairs are no longer distinct after moving the objective the above process is repeated until both image and cross-hairs are clearly seen **at the same instant**. The focus should be tested for parallax by moving the eye slightly from one side to the other; if the cross-hairs appear to move over the image the focus is imperfect. In focusing on objects at different distances it should be remembered that the nearer the object is to the telescope, the farther the objective must be from the cross-hairs; and that for points near the instrument the focus changes rapidly, i.e., the objective is moved considerably in changing from a focus on a point 10 ft. away to one 20 ft. away, whereas for distant objects the focus changes very slowly, the focus for 200 ft. being nearly the same as that for 2000 ft. An instrument can be quickly focused on a distant object if the objective is first moved in as far as it will go and then moved out slowly until the image is distinct. The objective should not be moved too rapidly as it may pass the correct position before the eye can detect the distinct image. If an instrument is badly out of focus it may be pointing directly at an object and yet the image may not be visible.

46. The Objective.—The objective might consist of a simple bi-convex lens, like that shown in Fig. 15, which is formed by the intersection of two spheres. The line OO' joining the centers of the two spheres is called the *optical axis*. If rays parallel to the optical axis fall on the lens those near the edge of the lens are bent, or refracted, more than those near the center, so that all the rays are brought to a focus (nearly) at a point F on the optical axis called the *principal focus*. If light falls on the lens from any direction there is one of the rays such as

AC or BD which passes through the lens without permanent deviation, i.e., it emerges from the other side of the lens parallel to its original direction. All such rays intersect at a point X on the optical axis which is called the *optical center*.

A simple bi-convex lens does not make the best objective because the rays do not all come to a focus at **exactly** the same point. This causes indistinctness and also color in the field of

FIG. 15. BI-CONVEX LENS.

view, particularly near the edges. This difficulty is overcome by using a combination of lenses, consisting of "crown" and "flint" glass as shown in Fig. 14, which very nearly corrects these imperfections.

The position of the image of any point is located on a straight line (nearly) through the point and the optical center; hence it will be seen that the image formed by the objective is inverted.

47. Cross-Hairs. — The cross-hairs consist of two very fine spider threads stretched across a metallic ring at right angles to each other and fastened by means of other and fastened by means

FIG. 10. CROSS-HAIR RING.

of shellac. The cross-hair ring (Fig. 16) is held in place by four capstan-headed screws which permit of its being moved

vertically or horizontally in the telescope tube. The holes in the tube through which the screws pass are large enough to allow some motion of the ring in adjusting.

48. Eyepiece. — The eyepiece of the ordinary transit telescope may be either of two kinds, that which shows an inverted image or that which shows an erect image. An erecting eyepiece requires two more lenses than the inverting eyepiece, which add to its length and also absorb light ; but in spite of these disadvantages the erecting eyepiece is generally used on ordinary transits. It will be seen, however, that with the same length of telescope a greater magnifying power and a clearer definition of the image can be obtained by the use of the inverting eyepiece. These advantages are so important and the disadvantage of seeing objects inverted is so slight that inverting eyepieces should be used more generally than they are at present.

49. Magnifying Power. — The magnifying power is the amount by which an object is increased in apparent size. It is equal to $\frac{\tan \frac{1}{2} A}{\tan \frac{1}{2} a}$, (or nearly equal to $\frac{A}{a}$), A being the angle subtended by an object as seen through the telescope and a the angle as seen by the unaided eye.

50. The magnifying power may be measured in two ways. (1) The dimensions on a graduated rod will appear magnified when viewed through a telescope. If, with one eye at the telescope, the rod is viewed directly with the other eye it will be noticed that one space as viewed through the telescope will appear to cover a certain number of spaces as seen with the naked eye. This number is approximately the magnifying power of the telescope.

(2) Viewed through a telescope wrong-end-to, an object is reduced in apparent size in the same ratio that it is magnified when seen through the telescope in the usual manner. Measure with a transit some small angle A between distant points and then place the telescope to be tested in front of the transit, with its objective next the objective of the transit. Measure the angle a between the same points ; this new angle will be smaller. Then

the Magnifying Power = $\frac{\tan \frac{1}{2} A}{\tan \frac{1}{2} a}$. The magnifying power

of the ordinary transit telescope is between twenty and thirty diameters.

51. Field of View.—The field of view is the angular space that can be seen at one time through the telescope. It is the angle subtended at the optical center of the objective by the opening in the eyepiece. In the ordinary transit this angle is about one degree, but in some instruments it is considerably more.

FIG. 17.

FIG. 18.

FIG. 19.

52. THE VERNIER.—The vernier is a device for determining the subdivision of the smallest division of a scale more accu-

rather than can be done by simply estimating the fractional part. It depends upon the fact that the eye can judge much more exactly when two lines coincide than it can estimate a fractional part of a space.

A simple form of vernier, shown in Fig. 17, is constructed by taking a length equal to 9 divisions on the scale and dividing this length into 10 equal parts. One space on the vernier is then equal to $\frac{9}{10}$ of a space on the scale, i.e., it is $\frac{1}{10}$ part shorter than a space on the scale, hence $ab = \frac{1}{10}$ of a space on the scale, $cd = \frac{2}{10}$ of a space, etc. Now if the vernier is raised until a coincides with b , i.e., until the first line on the vernier coincides with the next higher line on the scale, then the index line has moved over $\frac{1}{10}$ of a space and the reading will be 501. If the vernier is moved $\frac{1}{10}$ space higher then line 2 coincides with the next higher line on the scale and the reading is 502, as shown in Fig. 18. Similarly Fig. 19 shows reading 526. Thus it is seen that the number of the line on the vernier which coincides with a line on the scale is the number of tenths of the smallest division of the scale that the index point (zero) lies above the next lower division on the scale. Furthermore it will be seen from its construction that it is impossible to have more than one coincidence at a time on a single vernier. The type of vernier just described is used on leveling rods.

53. Verniers used on Transits.—In transits, since angles may be measured in either direction, the verniers are usually double, i.e., there is a single vernier on each side of the index point, one of which is to be used in reading angles to the right, and the other in reading angles to the left.

The vernier most commonly found on the transit reads to one minute of arc (Fig. 20). When this vernier is used the circle is divided into degrees and half-degrees. The vernier scale is made by taking a length equal to 29 of the half-degree spaces and subdividing it into 30 equal parts. Each space on the vernier is then equal to $\frac{29}{30} \times 30' = 29'$. Therefore the difference in length of one division on the circle and one division on the vernier is equal to the difference between the 30' on the circle and the 29' on the vernier, or one minute of arc. In

Fig. 20 the zero of the vernier coincides with the 0° mark on the circle. The first graduation on the vernier to the left of the zero fails to coincide with the $0^\circ 30'$ line by just $1'$ of arc. The second line on the vernier falls $2'$ short of the 1° mark, the third line $3'$ short of the $1^\circ 30'$ mark, etc. If the vernier should be moved one minute to the left the first line would coin-

FIG. 20. ONE-MINUTE VERNIER SET AT 0° .

cide and the reading would be $0^\circ 01'$. If the vernier were moved one minute more the second line would coincide and the reading would be $0^\circ 02'$, etc. Therefore the number of the line on the vernier which coincides with some line on the circle is the number of minutes to be added to 0° . After the vernier has moved beyond the point where the $30'$ line coincides, it begins subdividing the next space of the circle, and we must then add the vernier reading to $0^\circ 30'$.

The following figures show various types of vernier commonly used on transits.

FIG. 21.

Fig. 21. — Double vernier reading to 1'. Circle divided into 30' spaces. 29 divisions of the circle divided into 30 parts to make one division of the vernier.

Reading, outer row of figures, $9^{\circ} 16'$.

Reading, inner row of figures, $350^{\circ} 44'$.

Since the vernier moves with the telescope, **read the angle on the circle in the same direction that the telescope has moved.** Read the number of degrees and half-degrees the index has passed over and estimate roughly the number of minutes beyond the last half-degree mark. Then follow along the vernier in the **same** direction and find the coincidence. The number of this line is the number of minutes to be added to the degrees and half-degrees which were read from the circle. An estimate of the number of minutes should always be made as a check against large mistakes in reading the vernier or in reading the wrong vernier.

Fig. 22. — Double vernier reading to 30". Circle divided

FIG. 22.

into 20' spaces. 39 divisions of the circle divided into 40 parts to make one division of the vernier.

Reading, inner row of figures, $31^{\circ} 17' 30''$.

Reading, outer row of figures, $328^{\circ} 42' 30''$.

Fig. 23. — Single vernier reading to $20''$. Circle divided into $20'$ spaces. 59 divisions of the circle divided into 60 parts to make one division of the vernier.

Reading, $73^{\circ} 48' 40''$.

On account of the length of this vernier it is impracticable to use a double vernier. Where it is desirable to read the angles in either direction the circle has two rows of figures as shown in Fig. 24.

Fig. 24. — Reading, inner row of figures, $73^{\circ} 48' 40''$.
Reading, outer row of figures, $266^{\circ} 31' 20''$.

It is evident that if angles are to be read "clockwise" the index at the right end of this vernier should be set at 0° . If

angles are to be measured in the opposite direction the index at the left end should be set at 0° . To avoid this inconvenience of resetting, some surveyors set the middle line ($10'$ line) of the vernier on 0° and disregard the numbering on the vernier, reading it as explained under Fig. 26.

Fig. 25. — Single vernier reading to $10''$. Circle divided

FIG. 25.

into $10'$ spaces. 59 divisions of the circle divided into 60 parts to make one division of the vernier.

Reading, $59^\circ 15' 50''$.

Fig. 26. — Single vernier reading in either direction to $1'$.

FIG. 26.

Circle divided into $30'$ spaces. 29 divisions of the circle divided into 30 parts to make one division of the vernier.

Reading, $2^\circ 23'$.

This vernier is read like the ordinary 1' vernier except that if a coincidence is not reached by passing along the vernier in the direction in which the circle is numbered, it is necessary to go to the other end of the vernier and continue in the same direction, toward the center, until the coincidence is found. This vernier is used on the vertical circle of transits when the space is too small for a double vernier.

There is another type of transit vernier, which is occasionally used, in which the degree is divided into hundredths instead of minutes.

54. ECCENTRICITY. — If the two opposite verniers of a transit do not read exactly alike it is usually due to a combination of two causes, (1) because the center of the vernier plate does not coincide with the center of the graduated circle, (2) because the vernier zeros have not been set exactly 180° apart. The first cause produces a variable difference while the second produces a constant difference.

It will be noticed that the effect of these errors is similar to that described in Art. 34, p. 25, on Adjustments of the Compass; the eccentricity of the circles of the transit corresponding

to the bent pivot of the compass and the error in the position of the verniers of the transit corresponding to the bent needle of the compass.

FIG. 27. ECCENTRICITY OF CIRCLE.

With reference to the eccentricity of the plates, let C in Fig. 27 be the center of the vernier plate and C' the center of the circle. Let GF be a line through the two centers. When one vernier is at F and the other is at G the vernier readings will be the same as though C

and C' were coincident, since the displacement of the center of the circle occurs in the direction of the lines of graduation at F and G . If the telescope is then turned at right angles to its former position, the verniers then being at D and E , the readings

of opposite verniers will differ by the maximum amount. Suppose that the graduations are numbered from 0° right-handed to 360° . When the vernier is at an intermediate position, as at A , it will be seen that it reads too much by the amount AA' . The opposite vernier at B reads too little by the amount BB' . Since AB and $A'B'$ are parallel, BB' and AA' are equal. Consequently the mean of the two vernier readings will be the true reading and the eccentricity is in this way eliminated. Since the effect of eccentricity is never more than a very few minutes it is customary to read the degrees and minutes on one vernier and the minutes only on the other.

55. In spite of the fact that the two verniers are not 180° apart no error is introduced provided; (1) that the same vernier is always used, or (2) that the mean of the two vernier readings is always taken. But if vernier A is set and the angle is read on vernier B an error does enter. Where only one vernier is read **always read the vernier that was set at 0° .**

In good instruments both of these errors are very small, usually smaller than the finest reading of the vernier.

USE OF THE TRANSIT.

56. **SETTING UP THE TRANSIT.**—In setting the transit over a point, place one leg of the tripod in nearly the right position on the ground, then grasp the other two and move the instrument in such a way as to bring the head over the point and at the same time keep the plates of the instrument **approximately level**, giving the tripod sufficient spread to insure steadiness. The tripod legs should be pressed firmly into the ground. The nuts at the top of the tripod legs should be tight enough so that the legs are just on the point of falling of their own weight when raised from the ground. If they are loose the instrument is not rigid; if they are too tight it is not in a stable condition and may shift at any moment.

If the point is on sloping ground it is often convenient, and usually insures greater stability, to set two legs on the downhill side and one leg uphill. When the center of the instrument is over the point but the tripod head is not nearly level it can be

leveled approximately without moving the instrument away from the point by moving one, sometimes two, of the tripod legs in an arc of a circle about the point. Nothing but practice will make one expert in setting up the transit.

It is desirable to bring the instrument very nearly level by means of the tripod; this is really a saving of time because under ordinary conditions it takes longer to level up by the leveling screws than by the tripod. It also saves time on the next set-up to have the leveling screws nearly in their mid position. If the transit is set by means of the tripod, say, within 0.01 or 0.02 ft. of the point, the exact position can be readily reached by means of the *shifting head*, which may be moved freely after any two **adjacent** leveling screws are loosened. When the transit has been brought directly over the point, the leveling screws should be brought back to a bearing. In the first (rough) setting the plumb-bob should hang, say, an inch above the point, but when the shifting head is used it should be lowered to within about $\frac{1}{8}$ inch or less of the point.

57. In leveling the instrument, first turn the plates so that each plate level is parallel to a pair of **opposite** leveling screws.

FIG. 28. CUT SHOWING HOW FINGERS MOVE IN LEVELING.

Each level is therefore controlled by the pair of leveling screws which is parallel to it. Great care should be used in leveling. The screws must not be loose as this will cause the plates to tip and perhaps to move horizontally which would change the position of the plumb-bob over the point. On the other hand they

must not be too tight as this will not only injure the instrument but will cause errors due to strains in the metal. To level the instrument, grasp one pair of opposite screws between the thumbs and forefingers and turn so that the thumbs move either **toward** each other or **away from** each other, as illustrated in Fig. 28. In this way one screw is tightened as much as the other is loosened. The motion of both screws must be uniform ; if they bind, the one which is being loosened should be turned faster. If this does not appear to remedy matters then the other pair of screws is binding and should be loosened slightly. Only experience will teach one to level an instrument quickly and correctly. It may be convenient for beginners to remember that in leveling the instrument the bubble will move in the same direction as the left thumb moves. After one bubble has been brought nearly to the center of its tube the other bubble is centered in a similar manner by its pair of leveling screws. Instead of trying to center one bubble **exactly** before beginning on the second one it is better to get both of them approximately level, after which first one bubble and then the other may be brought exactly to the center. After the instrument is leveled the plumb-bob should be examined to see that it has not been moved from over the point during the process of leveling.

58. TO MEASURE A HORIZONTAL ANGLE. — After setting the instrument up over the point, first set the zero of one of the verniers opposite the zero of the circle. This is done by turning the two plates until the two zeros are nearly opposite, clamping the plates firmly together with the **upper clamp**, and then bringing the two into exact coincidence by means of the tangent screw which goes with the **upper clamp**. If a line on the vernier is coincident with a line on the circle then the two adjacent lines on the vernier will fail to coincide with the corresponding lines on the circle by **equal amounts** (Art. 53, p. 39). Hence the coincidence of any line on the vernier with a line on the circle can be more accurately judged by examining also the adjacent divisions and noting that they are symmetrical with respect to the coincident lines. A pocket magnifier, or "reading glass," is generally used for setting and reading the vernier. **Never touch the clamp after a setting has been made by means of the**

tangent screw. In setting with the tangent screw it is better to do this by a **right-hand turn**, i.e., by turning the screw in the direction which **compresses** the spring against which it works. If the screw needs to be turned back, instead of turning it to the exact setting turn it back too far and then bring it up to the accurate setting with a right-hand motion, thereby insuring a firm bearing of the spring against the screw. The two plates which are now clamped in proper position are free to turn together about the vertical axis. Turn to the first object and point the telescope at it approximately by looking over the top of the telescope. When turning the instrument so as to sight the first point it is good practice to touch the lower plate only. Focus the telescope by moving the eyepiece until the cross-hairs are distinct and then moving the objective until the image is distinct. It is sometimes convenient to point the telescope at the object when focusing the cross-hairs so that they can be readily seen.* Test for parallax by moving the eye slightly from one side to the other. Move the telescope until the vertical cross-hair is very nearly on the point. It is better to use that part of the cross-hair which is near the center of the field of view. Clamp the lower plate by means of the **lower clamp**, and set exactly on the point by the **lower tangent screw**. The line of sight is now fixed on the first object. To measure the angle loosen the **upper clamp**, turn the telescope to the second point, and focus the objective if necessary. Set nearly on the point, clamp the **upper plate**, and set the vertical cross-hair exactly on the point by means of the **upper tangent screw**. The angle is then read **on the vernier which was set at 0°**.

The tangent screws should **not** be used to move the plates over large angles. Acquire the habit of setting closely by hand and using the tangent screw for slight motions only.

59. TO MEASURE AN ANGLE BY REPETITION.—The eyepiece magnifies the image so much that it is possible to set the cross-hair on a point much more closely than the vernier will

* If the eyepiece is focused on the cross-hairs with the telescope pointing at the sky, as is frequently done, they will be found to be approximately in focus when looking at the object; but for accurate work the eyepiece should be focused on the cross-hairs when the objective is in focus on the object.

read. The graduation of the circle is very accurate and can be depended upon closer than the vernier can be read, consequently the full value of the instrument is not utilized by single readings of an angle. To obtain the value of an angle more accurately proceed as follows. After the first angle has been measured leave the two plates clamped together, loosen the **lower clamp** and turn back to the first point. Set on the first point, using the **lower clamp** and its tangent screw. Then loosen the upper clamp and set on the second point, using the **upper clamp** and its tangent screw, thus adding another angle, equal to the first one, to the reading on the circle. Repeat this operation, say, six times. The total angle divided by six will give a more precise result than the first reading. Suppose that the angle is actually $18^{\circ} 12' 08''$; if a "one-minute" instrument is being used it is impossible to read the $08''$ on the vernier, so the reading will be $18^{\circ} 12'$. Each repetition will add $08''$ (nearly) and after the 6th repetition, the amount will be $48''$ which will be read as $1'$. After the 6th pointing the total angle will then be read $109^{\circ} 13'$ which divided by 6 gives $18^{\circ} 12' 10''$, a result in this case correct to the nearest $10''$. To eliminate errors in the adjustment of the transit the above process should be repeated with the instrument reversed and the mean of the two values used. (See Art. 79, p. 61.) It is customary to take only the 1st and 6th readings, but as a check against mistakes it is well for the beginner to examine the vernier reading after each repetition and see that $\frac{1}{2}$ the second reading, $\frac{1}{3}$ the third, etc., nearly equals the first reading.

Repetition has also the advantage of eliminating, to a great extent, errors of graduation. If an angle is about 60° and is repeated 6 times it will cover a whole circumference. If there are systematic errors in the graduations the result is nearly free from them. The effect of accidental, or irregular, errors of graduation is decreased in proportion to the number of repetitions. In the best modern instruments the errors of graduation seldom exceed a few seconds.

Little is gained by making a very large number of repetitions as there are systematic errors introduced by the action of the clamps, and the accuracy apparently gained is really lost on this

account. Three repetitions with the telescope normal and three with the telescope inverted are sufficient for anything but very exact work.

It is desirable that as little time as possible should elapse between pointings, as the instrument cannot be relied upon to remain perfectly still. As a matter of fact it is vibrating and "creeping" nearly all the time from numerous causes. For example, when the instrument is set up on frozen ground, it will quickly change its position on account of the unequal settlement of the tripod legs. Changes of temperature, causing expansion or contraction of the metal of the instrument, and the effect of wind introduce errors. The more rapidly the measurements can be made, consistent with careful manipulation, the better the results will be. If the transit is set up on shaky ground the transitman should avoid walking around his instrument.

60. Repetition is useful not only to secure precision, but also as a check against mistakes. If a mistake is made on the first reading of an angle the vernier, on the second reading, falls in a new place on the circle so that the mistake is not likely to be repeated. It is common practice to repeat, or "double," all important angles and divide the second reading by 2 simply as a check on the first reading.

● 61. **TO LAY OFF AN ANGLE BY REPETITION.**— There is no direct method of laying off an angle by repetition as in the case of measuring an angle, therefore the following indirect method is used. With the vernier set at 0° and the telescope sighted on the first point the angle is carefully laid off on the circle and the second point set in line with the new position of the telescope. Then this angle which has been laid off is **measured** by repetition as precisely as is desired as described in Art. 59. The resulting angle obtained by repetition is a more precise value than the angle first set on the vernier. The difference between this value and the angle desired is the correction which should be made at the second point. This can be readily done by measuring approximately the distance from the instrument to the second point, and computing the perpendicular offset to be laid off at the second point. (The offset for an angle of one minute at a distance of 100 ft. is nearly 0.03 ft.)

62. RUNNING A STRAIGHT LINE — One Point Visible from the Other. — There are several ways in which a straight line may be fixed on the ground, depending upon the existing conditions. If the line is fixed by the two end points one of which is visible from the other, the method of setting intermediate points would be to set the transit over one point, take a "fore-sight" on the other and place points in line. For very exact work the instrument should be used in both the direct and reversed positions (Art. 79, p. 61). This will eliminate errors of adjustment such as failure of the telescope to revolve in a true vertical plane, or failure of the objective tube to travel parallel to the line of sight.

63. RUNNING A STRAIGHT LINE — Neither Point Visible from the Other. — If neither point can be seen from the other then it is necessary to find some point, by trial, from which the terminal points can be seen. The transit is set up at some point estimated to be on the line, a "backsight" is taken on one of the points and the instrument clamped. The telescope is then reversed on its horizontal axis. If the vertical cross-hair strikes the second point the instrument is in line; if not, then the error in the position of the instrument must be estimated (or measured) and a second approximation made. In this way, by successive trials, the true point is attained. The final tests should be made with the instrument in direct and reversed positions to eliminate errors of adjustment of the line of sight and the horizontal axis. To eliminate errors in the adjustment of the plate bubbles the plate level which is perpendicular to the line should be releveled just before making the second backsight and while the telescope is pointing in that direction. This can be more readily done if, when the transit is set up, one pair of opposite leveling screws is turned so as to be in the direction of the line; then the other pair will control the level which is perpendicular to the line of sight. After one point has been found by this method other points may be set as described in the previous article.

Another method of running a line between two points one of which is not visible from the other would be to run what is called a *random line* as described in Art. 191, p. 169.

64. Prolonging a Straight Line. — If a line is fixed by two points *A* and *B* and it is desired to prolong this line in the direction *AB*, the instrument should be set up at *A*, a sight taken on *B* and other points set in line beyond *B*. When it is not possible to see beyond *B* from *A*, the transit should be set up at *B* and points ahead should be set by the method of backsighting and foresighting as follows. With the transit at *B* a backsight is taken on *A* and the instrument clamped. The telescope is inverted and a point set ahead in line. The process is repeated, the backsight being taken with the telescope in the inverted position. The mean of the two results is a point on the line *AB* produced. The transit is then moved to the new point, a backsight is taken on *B*, and another point set ahead as before.

In this last case, if a line is prolonged several times its own length by backsighting and foresighting, there is likely to be a constantly increasing error. In the first case, where the line is run continually toward a point known to be correct, the errors are not accumulating.

65. Methods of Showing Sights. — If the point sighted is within a few hundred feet of the instrument, a pencil may be used and held vertically in showing a point for the transitman to sight on. Sighting-rods are used on long distances.* Where only the top of the rod or pole is visible a considerable error is introduced if it is not held plumb. A plumb-line is much more accurate for such work but cannot be easily seen on long sights. Under conditions where the plumb-line cannot be readily seen some surveyors use for a sight an ordinary white card held with **one edge** against the string or held so that the **center** of the card is directly behind the string. If the edge of the card is held against the string, the transitman must be **extremely** careful that he is sighting on the proper edge.†

* It is desirable that the foresight should be of a color such that the cross-hair is clearly seen, and of a width such that the cross-hair nearly (but not quite) covers it.

† It is common among some surveyors to use a two-foot rule for a sight. The rule is opened so that it forms an inverted V (Δ). The plumb-string is jammed into the angle of the Δ by pressing the two arms of the rule together. The rule is then held so that the plumb-string as it hangs from the rule appears to bisect the angle of the Δ .

Another device is to attach to the plumb-line an ordinary fish-line float (shaped

Whenever the instrument is sighted along a line which is to be frequently used or along which the transit is to remain sighted for any considerable time the transitman should if possible select some well-defined point which is in the line of sight, called a "foresight." If no definite point can be found one may be placed in line for his use. By means of this "foresight" the transitman can detect if his instrument moves off the line, and can set the telescope exactly "on line" at any time without requiring the aid of another man to show him a point on the line.

66. Signals. — In surveying work the distances are frequently so great that it is necessary to use hand signals. The following are in common use.

"*Right*" or "*Left*." — The arm is extended in the direction of the motion desired, the right arm being used for a motion to the right and the left arm for a motion to the left. A slow motion is used to indicate a long distance and a quick motion a short distance.

"*Plumb the Pole*." — The hand is extended vertically above the head and moved slowly in the direction it is desired to have the pole plumbed.

"*All Right*." — Both arms are extended horizontally and moved vertically.

"*Give a Foresight*." — The transitman, desiring a foresight, motions to the rodman, by holding one arm vertically above his head.

"*Take a Foresight*." — The rodman desiring the transitman to sight on a point, motions the transitman by holding one arm vertically above his head and then he holds his lining-pole vertically on the point.

"*Give Line*." — When the rodman desires to be placed "on line" he holds his lining-pole horizontally with both hands over his head and then brings it down to the ground in a vertical position. If the point is to be set carefully, as a transit point,

like a plumb-bob). This may be fastened so that its axis coincides with the string and so that it can be raised and lowered on the string. It should be painted with such colors that it can be seen against any background.

The man showing the sight for the transitman should always try to stand so that the sun will shine on the object he is holding; on long sights it is difficult (sometimes impossible) to see an object in a shadow.

the rodman waves the top end of pole in a circle before bringing it to the vertical position.

"Pick up the Transit." — When the chief of the party desires to have the instrument set at another point he signals to the transitman by extending both arms downward and outward and then raising them quickly.

All signals should be distinct so as to leave no doubt as to their meaning. Care should be taken to stand so that the background will not prevent the signals being distinctly seen. The palms of the hands should be shown in making the signals, and for distant signals a white handkerchief is often used. Where much distant signaling is to be done flags are attached to the lining-poles. Special signals may be devised for different kinds of work and conditions.

67. TO MEASURE A VERTICAL ANGLE. — In measuring a vertical angle with a transit, first point the vertical cross-hair approximately at the object, then set the horizontal cross-hair exactly on the point by means of the clamp and tangent screw controlling the vertical motion. Next read the vertical arc or circle. Then, **without disturbing the rest of the transit**, unclamp the vertical arc, and bring the telescope to the horizontal position by means of the level attached to the telescope, and the clamp and tangent screw of the vertical arc. When the telescope bubble is in the center read the vertical arc again. This gives the *index correction*, to be added or subtracted according to whether the two readings are on opposite or on the same side of zero. In some forms of transit the vernier is on a separate arm which also carries a level. By bringing this level to the center of the tube by means of its tangent screw the index correction is reduced to zero each time and the true angle read directly. Instruments provided with this form of level have no level attached to the telescope.

If the transit has a complete vertical circle errors in the adjustment of the bubble and the horizontal cross-hair may be eliminated by inverting the telescope, turning it through 180° azimuth, and remeasuring the angle. The mean of the two results is free from such errors. If the transit is provided with only a portion of a circle the vernier will be off the arc when

the telescope is inverted, consequently with a transit of this type the elimination cannot be effected.

68. PRECAUTIONS IN THE USE OF THE TRANSIT.— In the preceding text several sources of error and also precautions against mistakes have been mentioned, but in order that the beginner may appreciate the importance of handling the instrument carefully he should make the following simple tests.

1. Set the transit up with the three points of the tripod rather near together so that the instrument will be high and unstable. Sight the cross-hair on some definite object, such as the tip of a church spire, so that the slightest motion can be seen. Take one tripod leg between the thumb and forefinger and twist it strongly; at the same time look through the telescope and observe the effect.

2. Press the tripod leg laterally and observe the effect on the level attached to the telescope; center the bubble before testing.

3. Step on the ground about 1 or 2 inches from the foot of one of the tripod legs and observe the effect on the line of sight.

4. Breathe on one end of the level vial and observe the motion of the bubble.

5. Press laterally on the eyepiece and observe the effect on the line of sight.

These motions, plainly seen in such tests, are really going on all the time, even if they are not readily apparent to the observer, and show the necessity for careful and skillful manipulation. The overcoat dragging over the tripod, or a hand carelessly resting on the tripod, are common sources of error in transit work.

Before picking up the transit **center the movable head, bring the leveling screws back to their mid position, loosen the lower clamp, and turn the telescope either up or down.**

ADJUSTMENTS OF THE TRANSIT.

69. If an instrument is badly out of adjustment in all respects, it is better not to try to completely adjust one part at a time but to bring the instrument as a whole gradually into adjustment. If this is done, any one process of adjusting will not disturb the preceding adjustments, the parts are not subjected to strains, and the instrument will be found to remain in adjustment much longer than it would if each adjustment were completed separately.

Nearly all adjustments of the transit, in fact of nearly all surveying instruments, are made to depend on the principle of *reversion*. By reversing the position of the instrument the effect of an error is doubled.

70. ADJUSTMENT OF THE PLATE BUBBLES. — To adjust the Plate Levels so that Each lies in a Plane Perpendicular to the Vertical Axis of the Instrument. Set up the transit and bring

FIG. 29. ADJUSTMENT OF THE PLATE BUBBLES.

the bubbles to the center of their respective tubes. Turn the plate 180° about its vertical axis and see if the bubbles remain in the center. If they move from the center, half this distance is the error in the adjustment of the tube. (See Fig. 29.) The adjustment is made by turning the capstan-headed screws on the

bubble tube until the bubble moves half-way back to the center as nearly as this can be estimated. Each bubble must be adjusted independently. The adjustment should be tested again by releveled and reversing as before, and the process continued until the bubbles remain in the center when reversed. When both levels are adjusted the bubbles should remain in the centers during an entire revolution about the vertical axis.

71. ADJUSTMENT OF THE CROSS-HAIRS. — 1st. To put the **Vertical Cross-Hair in a Plane Perpendicular to the Horizontal Axis.** Sight the vertical hair on some well-defined point, and, leaving both plates clamped, rotate the telescope slightly about the horizontal axis (see Fig. 30).

The point should appear to travel on the vertical cross-hair throughout its entire length. If it does not, loosen the screws

FIG. 30. ADJUSTMENT OF THE CROSS-HAIRS (FIRST PART).

holding the cross-hair ring, and by tapping lightly on one of the screws, rotate the ring until the above condition is satisfied. Tighten the screws and proceed with the next adjustment.

72. 2nd. To make the Line of Sight Perpendicular to the Horizontal Axis.* (See Fig. 31.) Set the transit over a point

FIG. 31. ADJUSTMENT OF THE CROSS-HAIRS (SECOND PART).

A. Level up, clamp both plates, and sight accurately on a point *B* which is approximately at the same level as *A*. Reverse the telescope and set *C* in line with the vertical cross-hair. *B*, *A*, and *C* should be in a straight line. To test this, turn the instrument about the vertical axis until *B* is again sighted. Clamp the plate, reverse the telescope, and observe if point *C* is in line. If not, set point *D* in line just to one side of *C* and then the cross-hair ring must be moved until the vertical hair appears to have moved to point *E*, **one-fourth** the distance from *D* toward *C*, since, in this case, a **double reversal** has been made.

The cross-hair ring is moved by loosening the screw on one side of the telescope tube and tightening the opposite screw. If *D* falls to the **right** of *C* then the cross-hair ring should be moved to the **left**; but if the transit has an erecting eyepiece the cross-hair will **appear** to move to the **right** when viewed through the telescope. If the transit has an inverting eyepiece the cross-hair appears to move in the same direction in which the cross-hair is actually moved.

The process of reversal should be repeated until no further adjustment is required. When finally adjusted, the screws should hold the ring firmly but without straining it.

* In making the adjustment in the shop with collimators instrument makers seldom level the transit carefully. In field adjustments it is desirable, although not necessary, to level the instrument. The essential condition is that the vertical axis shall not alter its position.

73. ADJUSTMENT OF THE STANDARDS. — To make the Horizontal Axis of the Telescope Perpendicular to the Vertical Axis of the Instrument. (See Fig. 32.) Set up the transit and sight the vertical cross-hair on a high point *A*, such as the top of a church steeple. Lower the telescope and set a point *B* in line, on the same level as the telescope. Reverse the telescope, turn the instrument about its vertical axis, and sight on *B*. Raise the telescope until the point *A* is visible and see if the cross-hair comes on *A*. If not, note point *C* in line and at same height as *A*. Then half the distance from *C* to *A* is the error of adjustment. Loosen the screws in the pivot cap and raise or lower the adjustable end of the horizontal axis by means of the capstan-headed screw under the end of the axis. Repeat the test until the high and the low points are both on the cross-hair in either the direct or reversed positions of the transit. The adjusting screw should be brought into position by a right-hand turn, otherwise the block on which the horizontal axis rests may stick and not follow the screw. The cap screws should then be tightened just enough to avoid looseness of the bearing.

FIG. 32. ADJUSTMENT OF THE STANDARDS.

74. Adjustment of the Telescope Bubble. — This is adjusted by the "*peg*" method, or *direct method*, as explained in Art. 128, p. 91. This consists in first determining a level line by using the instrument in such a way as to eliminate the error of the bubble, and then centering the bubble while the line of sight is horizontal.

75. Adjustment of the Auxiliary Level on the Vernier of the Vertical Arc. — (See Art. 67, p. 54.) To adjust the Level so that it is in the Center of the Tube when the Line of Sight is Level and the Vernier reads 0°. This is adjusted by the "*peg*"

method" (Art. 128, p. 91). The bubble is first brought to the center of the tube by means of its tangent screw. Then the telescope is moved until the vernier of the vertical arc reads 0° . The instrument is then in condition to be used as a leveling instrument and is adjusted by the "peg method."

If the telescope is provided with an attached level the auxiliary level could be adjusted by comparing it with the telescope level as follows. Level the telescope by means of its attached level, make the vernier read 0 by means of the tangent screw of the vernier, and then bring the bubble of the auxiliary level to the center by means of its adjusting screws.

76. Adjustment of the Vernier of the Vertical Circle.—To make the Vernier read 0° when the Telescope Bubble is in the Center of the Tube. If there is any index error (Art. 67, p. 54) bring the bubble to the center, loosen the screws holding the vernier, and tap lightly until the zeros coincide. Tighten the screws and test again. In some instruments the vernier is controlled by a slow-motion screw for setting the index at the zero of the circle.

77. Adjustment of the Objective Slide.—To make the Objective Slide move Parallel to the Line of Sight. If the tube holding the objective is adjustable it must be placed so that the direction of the line of sight will not be disturbed when the telescope is focused. The adjustment may be made as follows. Adjust the line of sight as in Art. 72, using very distant points. This will require the objective to be drawn in nearly as far as it will go and hence the position of the objective will be changed but little by any subsequent lateral adjustment of the tube. Next repeat the test for the adjustment of the line of sight by using two points which are very near the instrument. In sighting on these points the objective must be run out and any error in its adjustment will change the direction of the line of sight so that it is no longer perpendicular to the horizontal axis of the instrument. In case the instrument fails to stand this test the objective slide does not move parallel to the line of sight. The adjustment is made by moving the adjustment screws of the objective slide so as to apparently increase the error making, by estimation, one-quarter the correction required.

The adjustment of the line of sight should be again tested on two distant points and the cross-hairs moved in case the second adjustment appears to have disturbed the first.

78. SHOP ADJUSTMENTS. — The adjustment of the objective slide and other adjustments such as centering the eyepiece tube and centering the circles are usually made by the instrument maker.

79. HOW TO ELIMINATE THE EFFECT OF ERRORS OF ADJUSTMENT IN THE TRANSIT. — Errors of adjustment in the plate bubble may be avoided by leveling up and reversing as when adjusting. Then, instead of altering the adjustment, simply move the bubble half-way back by means of the **leveling screws**. This makes the vertical axis truly vertical. Then the bubbles should remain in the same parts of their respective tubes as the instrument revolves about its vertical axis.

Errors of the line of sight and errors of the horizontal axis are eliminated by using the instrument with the telescope in the direct and then in the reversed position and taking the mean of the results whether the work is measuring angles or running straight lines.

Errors of eccentricity of the circle are completely eliminated by reading the two opposite verniers and taking the mean.

Errors of graduation of the circle are nearly eliminated by reading the angle in different parts of the circle or by measuring the angle by repetition.

80. Care of Instruments. — A delicate instrument like the transit requires constant care in order that the various parts may not become loose or strained. Care should be taken that the tripod legs do not move too freely, and that the metal shoes on the feet of the tripod do not become loose. The transit should be securely screwed to the tripod. In caring for the lenses a camel's hair brush should be used for dusting them and soft linen with alcohol for cleaning them. The objective should not be unscrewed except when absolutely necessary, and when replaced it should be screwed in to the reference mark on the barrel of the telescope. Grease should never be used on exposed parts of an instrument, as it collects dust. Care should be taken not to strain the adjusting screws in making adjustments.

The instrument should be protected as much as possible from the sun, rain, and dust. If the instrument is carried in the box it is less likely to get out of adjustment than when carried on the shoulder, but the former is often inconvenient. It is customary in traveling by carriage or rail to carry the transit in its box. While being carried on the shoulder the lower clamp should be left unclamped so that in case the instrument strikes against anything, some parts can give easily and save the instrument from a severe shock. When the transit is in use, be careful not to clamp it too hard, but clamp it firmly enough to insure a positive working of the tangent screws and so that no slipping can occur.

81. COMMON SOURCES OF ERROR IN TRANSIT WORK. —

1. Nonadjustment, eccentricity of circle, and errors of graduation.
2. Changes due to temperature and wind.
3. Uneven settling of tripod.
4. Poor focusing (parallax).
5. Inaccurate setting over point.
6. Irregular refraction of atmosphere.

82. COMMON MISTAKES IN TRANSIT WORK. —

1. Reading in the wrong direction from the index on a double vernier.
2. Reading the opposite vernier from the one which was set.
3. Reading the circle wrong, e.g., reading 59° for 61° . If the angle is nearly 90° , reading the wrong side of the 90° point, e.g., 88° for 92° .
4. Using the wrong tangent screw.

FIG. 33. SOLAR ATTACHMENT TO TRANSIT.

(The authors are indebted to C. L. Berger & Son
for the photograph from which this cut was made.)

THE SOLAR ATTACHMENT.

83. DESCRIPTION OF SOLAR ATTACHMENT. — One of the most important auxiliaries to the engineer's transit is the solar attachment, one form of which is shown in Fig. 33. This is a small instrument which may be attached to the telescope and by means of which a true meridian line can be found by an observation on the sun. In the form here shown the principal parts are the *polar axis*, which is attached to the telescope perpendicular to the line of sight and to the horizontal axis, and a small telescope which is mounted on the polar axis. This telescope can be revolved about the polar axis and can be inclined to it at any desired angle. The polar axis is provided with four adjusting screws for making it perpendicular to the line of sight and to the horizontal axis.

Another form of attachment has the solar telescope replaced by a lens and a screen on which the sun's image can be thrown. This defines a line of sight and is in reality the equivalent of a telescope. This instrument is provided with the arc of a circle known as the *declination arc*, the use of which will be explained later.

Still another form consists of a combination of mirrors (similar to those of a sextant) which can be placed in front of the objective. In this form the telescope of the transit serves as the polar axis.

While these various solar attachments differ in the details of construction, they all depend upon the same general principles.

84. THE CELESTIAL SPHERE. — In order to understand the theory of this instrument it will be necessary to define a few astronomical terms. Fig. 34 represents that half of the celestial sphere which is visible at one time to an observer on the surface of the earth. For the purposes of this problem the celestial sphere may be regarded as one having its center at the center of the earth and a radius equal to the distance of the sun from the earth. The sun in its apparent daily motion would then move around in a circle on the surface of this

sphere. The circle $NESW$ is the observer's *horizon* and is the boundary between the visible and invisible parts of the celestial sphere. The point Z is the *zenith* and is the point where a plumb-line produced would pierce the celestial sphere. The circle $SZPN$ is the observer's *meridian* and is a vertical circle through the pole. The circle EQW is the *celestial equator*. The circle AMB , parallel to the equator, is a *parallel of declination*, or the path described by the sun in its apparent daily

FIG. 34. DIAGRAM OF THE CELESTIAL HEMISPHERE.

motion from east to west. The *sun's declination* is its angular distance from the equator, or the arc OT . The declination is considered **positive** when north and **negative** when south. The *polar distance* of the sun is the complement of the declination represented by the arc OP .

85. OBSERVATION ON THE SUN FOR MERIDIAN WITH SOLAR ATTACHMENT.— If the polar axis of the instrument is made to point to the celestial pole, i.e., made parallel to the earth's axis, then the small telescope can be made to follow the sun in its daily path by simply giving it an inclination to the polar axis equal to the sun's polar distance and revolving it about the polar axis.

(1) To find the true meridian by an observation on the sun first make the angle between the polar axis and the solar telescope equal to the sun's polar distance at the time of the observation. This is done by turning the solar telescope into the same plane as the main telescope by sighting both on some distant object, and then making the angle between the two telescopes equal to the sun's declination. Some instruments are provided with a *declination arc* upon which the declination angle can be laid off directly. Others have a small spirit level attached to the small telescope, in which case the vertical circle of the transit is used for laying off the declination angle. Incline the main telescope until the reading of the vertical circle equals the declination, and clamp; then level the solar telescope by means of the attached level. The angle between the polar axis and the solar telescope is then 90° plus or minus the reading of the vertical circle.

(2) By means of the vertical circle of the transit incline the polar axis to the vertical by an angle equal to the **co-latitude of the place**, which is 90° minus the latitude. The polar axis now has the same angle of elevation as the celestial pole.

(3) If the observation is in the forenoon, place the solar telescope on the left of the main telescope (on the right if in the afternoon); then, by moving the whole instrument about the vertical axis and the solar telescope about the polar axis, point the solar telescope at the sun. The sun's image is brought to the center of the square formed by four cross-hairs, or ruled lines, in the solar telescope. The final setting is made by the tangent screw controlling the horizontal motion of the transit and the one controlling the motion of the solar about the polar axis. **Only one position can be found where the solar telescope will point to the sun.** In this position the vertical axis points to the zenith, the polar axis to the pole, and the solar telescope to the sun. The instrument has thus solved mechanically the spherical triangle having these three points (Z, P, O) as vertices. The horizontal angle between the two telescopes is equal to the sun's true bearing. Since the solar telescope is pointing to the sun the main telescope must be in the plane of the meridian. If all of the work has been correctly done it will be observed

that the sun's image will remain between the cross-hairs set parallel to the equator, and therefore the sun can be followed in its path by a motion of the solar telescope alone. If it is necessary to move the instrument about the vertical axis to point the solar telescope again at the sun this shows that the main telescope was not truly in the meridian.

After the meridian has been determined the main telescope may then be lowered and a point set which will be due north or due south of the instrument.

86. Computation of Declination Settings. — The sun's polar distance may be obtained from the "American Ephemeris and Nautical Almanac," published by the Government. The polar distance is not given directly, but its complement, the *sun's apparent declination*, is given for each day and for the instant of *Greenwich Mean Noon*. The rate of change of the declination, or the *difference for 1 hour*, is also given. In order to use this for any given locality, it is first necessary to find the local or the standard time corresponding to mean noon of Greenwich. In the United States, where standard time is used, the relation to Greenwich time is very simple. In the *Eastern* time belt the time is exactly 5 hours earlier than at Greenwich; in the *Central*, 6 hours earlier; in the *Mountain*, 7 hours earlier; in the *Pacific*, 8 hours earlier. If a certain declination corresponds to Greenwich mean noon, then the same declination corresponds to 7 A.M. in the Eastern belt or 6 A.M. in the Central belt, etc. The declination for any subsequent hour of the day may be found by adding (algebraically) the difference for 1 hour multiplied by the number of hours elapsed. Declinations marked *North* must be regarded as **positive** and those marked *South* as **negative**. An examination of the values of the declination for successive days will show which way the correction is to be applied. It will be useful also to remember that the declination is 0° about March 21, and increases until about June 22, when it is approximately $23^\circ 27'$ North; it then decreases, passing the 0° point about September 22, until about December 21 when it is approximately $23^\circ 27'$ South; it then goes North until March 21 when it is 0° again.

After the correct declination is found it has still to be cor-

rected for refraction of the atmosphere. The effect of refraction is to make the sun appear higher up in the sky than it actually is. In the northern hemisphere, when the declination is North this correction must be added, when South, subtracted; or algebraically it is always added.

The refraction correction may be taken from Table VII, p. 507.

The co-latitude which must be set off on the vertical circle may be obtained from a map or may be determined by an observation which is made as follows. Set off the sun's declination for noon, as for any other observation, the two telescopes being in the same vertical plane, and point the small telescope at the sun. By varying the angle of elevation of the main telescope, keep the solar telescope pointing at the sun until the maximum altitude is reached. The angle read on the vertical circle is the co-latitude (see also Art. 217, p. 196).

EXAMPLE.

Latitude 40° N.

Longitude $4^{\text{h}} 45^{\text{m}}$ W.

Jan. 10, 1900.

Declination for Greenwich mean noon $21^{\circ} 59' 04''$

Difference for 1h $+ 22''.25$

TIME.	DECLINATION.	REFRACTION.	SETTING.
7 h. A.M.	$21^{\circ} 59' 04''$		
8	58 42	5' 40"	$21^{\circ} 53' 02''$
9	58 20	2 51	21 55 29
10	57 57	2 07	21 55 50
11	57 35	1 51	21 55 44
12 M.	57 13	(1 47)	(21 55 26)
1 P.M.	56 51	1 51	21 55 00
2	56 28	2 07	21 54 21
3	56 06	2 51	21 53 15
4	55 44	5 40	21 50 04

87. * Comstock's Method of finding the Refraction. — Set the vertical cross-hair on one edge (or *limb*) of the sun and note the instant by a watch. Set the vernier of the plate $10'$ ahead and note the time when the limb again touches the cross-hair.

* See Bulletin of the University of Wisconsin, Science Series, Vol. I, No. 3.

Call the number of seconds between these observations n . Read the altitude h . Then the refraction in minutes will be nearly equal to $\frac{2000}{hn}$.

88. Observation for meridian should not be made when the sun's altitude is less than about 10° , because the refraction correction will be unreliable. Observations near noon are to be avoided because a slight error in altitude produces a large error in the resulting meridian. For good results therefore the observation should be made neither within an hour of noon nor near sunrise or sunset.

89. MISTAKES IN USING THE SOLAR ATTACHMENT. —

1. Solar on wrong side of main telescope.
2. Refraction correction applied wrong way.

ADJUSTMENTS OF THE SOLAR ATTACHMENT.

90. **ADJUSTMENT OF POLAR AXIS.** — To make the Polar Axis Perpendicular to the Plane of the Line of Sight and the Horizontal Axis. Level the transit and the main telescope. Bring the bubble of the solar telescope to the center of its tube while it is parallel to a pair of opposite adjusting screws which are at the foot of the polar axis. Reverse the solar telescope 180° about the polar axis. If the bubble moves from the center position, bring it half-way back by means of the adjusting screws just mentioned and the other half by means of the tangent screw controlling the vertical motion of the solar. This should be done over each pair of opposite adjusting screws and repeated until the bubble remains central in all positions.

91. **ADJUSTMENT OF THE CROSS-HAIRS.** — To make the Vertical Cross-Hair truly Vertical. Sight on some distant point with all the clamps tightened and, by means of the tangent screw controlling the vertical motion of the solar, revolve the solar telescope about its horizontal axis and see if the vertical cross-hair remains on the point. If not, adjust by rotating the cross-hair ring, as described in Art. 71, p. 57.

92. ADJUSTMENT OF TELESCOPE BUBBLE. — To make the Axis of the Bubble Parallel to the Line of Sight. Level the main telescope and mark a point about 200 ft. from the instrument in line with the horizontal cross-hair. Measure the distance between the two telescopes and lay this off above the first point which will give a point on a level with the center of the solar telescope. Sight the solar at this point and clamp. Bring the bubble to the center by means of the adjusting screws on the bubble tube.

PROBLEMS.

1. Is it necessary that the adjustments of the transit should be made in the order given in this chapter? Give your reasons.

2. A transit is sighting toward B from a point A . In setting up the transit at A it was carelessly set 0.01 ft. directly to one side of A , as at A' . What would be the resulting error, i.e., the difference in direction (in seconds) between AB and $A'B$, (1) when $AB = 40$ ft., (2) when $AB = 1000$ ft.?

3. An angle of 90° is laid off with a "one minute" transit, and the angle then determined by six repetitions, the final reading being $179^\circ 58' + 360''$. The point sighted is 185 feet from the transit. Compute the offset to be laid off in order to correct the first angle. Express the result in feet and also in inches.

4. An angle measured with a transit is $10^\circ 15' 41''$. The telescope of a leveling instrument is placed in front of the transit (with its objective toward the transit) and the angle again measured and found to be $0^\circ 18' 22''$. What is the magnifying power of this level telescope?

5. Compute the declination setting for every hour when observations on the sun for meridian can be made at Boston (Lat. $42^\circ 21' N$, Long. $71^\circ 04' 30'' W$) on each of the following dates.

January 1, 1906.

Decl. $S\ 23^\circ 03' 27''.9$

Diff. for 1 hour, $+ 11''.70$

April 16, 1906.

Decl. $N\ 9^\circ 53' 34''.2$

Diff. for 1 hour, $+ 53''.44$

July 2, 1906.

Decl. $N\ 23^\circ 05' 49''.5$

Diff. for 1 hour, $- 10''.39$

Sept. 25, 1906.

Decl. $S\ 0^\circ 35' 49''.4$

Diff. for 1 hour, $- 58''.51$

CHAPTER IV.

MEASUREMENT OF DIFFERENCE OF ELEVATION.

93. LEVEL SURFACE. — A level surface is a **curved** surface which at every point is perpendicular to the direction of gravity at that point, such, for example, as the surface of still water. Any line of sight which is perpendicular to the direction of gravity at a given point is therefore tangent to the level surface at that point and is called a *horizontal line*.

94. The Spirit Level. — In nearly all instruments the direction of gravity is determined by means of either a plumb-line or a spirit level. A spirit level is a glass tube, the inside of which is ground to a circular curve longitudinally, and nearly filled with a liquid such as alcohol or ether, leaving enough space to form a bubble. The grinding is usually done only on the inside upper surface of the tube. The radius of the curve varies according to the use which is to be made of the level; a very short radius makes a slow moving bubble while a long radius makes a very sensitive bubble. It is important that the curve should be exactly circular so that equal distances on the tube should subtend equal angles at the center. The level is provided with a scale of equal parts, which may be either a metallic scale screwed to the brass case holding the glass bubble tube, or it may consist of lines etched on the glass itself. A point near the middle of the tube is selected as the *zero point* and the graduations are numbered both ways from that point. The straight line tangent to the curve at the zero point of the scale is called the *axis of the bubble*. The position of the bubble in the tube is determined by noting the positions of both ends. The bubble will change its length with changes in temperature, consequently the reading of one end is not sufficient to determine the position of the bubble. On account of the action of gravity the bubble will always move toward the higher end of the tube; hence, when the bubble is **central** the axis of the tube is **horizontal**.

95. Angular Value of One Division of the Level Tube. — The angular value of one division of a level tube is the angle, usually expressed in seconds, through which the axis of the tube must be tilted to cause the bubble to move over the length of one division on the scale. The simplest way of finding this in the field consists in moving the bubble over several divisions on the scale by means of the leveling screws and observing the space on a rod passed over by the horizontal cross-hair, the rod being placed at a known distance from the instrument. The space on the rod divided by the distance to the rod gives the natural tangent of the angle through which the line of sight has moved. Since the angle is very small its value in seconds of arc may be obtained by dividing its tangent by the tangent of one second, ($\log \tan 1'' = 4.6855749 - 10$). Dividing the angle found by the number of divisions of the scale passed over on the bubble tube, gives a result which is the average number of seconds corresponding to a single division.

In a properly constructed leveling instrument the value of one division of the level should have a definite relation to the magnifying power of the telescope. The smallest angular movement that can be detected by the level bubble should correspond to the smallest movement of the cross-hairs that can be detected by means of the telescope.

THE LEVEL.

96. The instruments chiefly used for the direct determination of differences of elevation are known as the *Wye Level*, the *Dumpy Level*, and the *Hand Level*. The *Precise Level* differs in its details from the others but does not really constitute a different type; it is essentially a wye level or a dumpy level, according to the principle of its construction. The engineer's transit, which has the long level attached to the telescope, is frequently used for direct leveling. All of these instruments are so constructed that the line of sight is horizontal when the bubble of the attached spirit level is in the middle of its tube.

97. THE WYE LEVEL. — In the wye level (Figs. 35 and 36) the spirit level is attached to the telescope tube which rests in

FIG. 35. LONGITUDINAL SECTION OF A WYE LEVEL.

two Y shaped bearings from which it derives its name. Those parts of the telescope which bear on the wyes are made cylindrical and are called *rings* or *pivots*. The telescope is held in the wyes by means of two *clips*. The level is attached to the telescope by means of screws which allow vertical and lateral adjustments. The two wye supports are secured, by means of adjusting screws, to a horizontal bar which is attached rigidly at right angles to a spindle, or vertical axis, similar to that of a transit. The instrument is provided with leveling screws, clamp, and tangent screw, but has no shifting head nor plumb-line attachment. The whole upper portion of the instrument is screwed to a tripod in the same manner as a transit. The characteristic feature of the wye level is that the telescope can be lifted out of its supports, turned end for end and replaced, each ring then resting in the opposite wye.

98. THE DUMPY LEVEL. —

In the dumpy level (Fig. 37) the telescope, the vertical supports, the horizontal bar and the vertical spindle are all made in one casting or else the parts are fastened together rigidly so as to be essentially one piece. The

spirit level is fastened to the horizontal bar and can be adjusted in the vertical plane; there is no other adjustable part except the cross-hair ring.

99. Comparison of Wye and Dumpy Levels. — The wye level has long been a favorite in this country, chiefly on account of the ease with which it can be adjusted, which depends upon the fact that when the telescope is reversed in the wye supports the line through the centers of the pivots is exactly coincident with its first position. While this feature of the wye level is of practical advantage in adjusting the instrument it is based on the assumption that both pivots are **circular** and of **exactly the same diameter**, which may or may not be true. For, even supposing the pivots to be perfect when new, they soon wear, and perhaps unevenly, and consequently the method of adjusting by reversal will then fail and the "*peg*" *adjustment*, or *direct* method, must be used. (See Art. 128, p. 91) It is not uncommon to find a wye level of excellent manufacture which, after being adjusted by reversals, fails to stand the test by the direct method, but which is capable of excellent work when adjusted by the latter method.

The dumpy level has very few movable parts, and consequently it does not easily get out of adjustment even when subjected to rough usage.* Furthermore the recent work of the United States Coast and Geodetic Survey with a new precise level, which is really a dumpy level with certain refinements, indicates the superiority of the dumpy form for the most precise work.

FIG. 38. THE LOCKE HAND LEVEL.

100. THE LOCKE HAND LEVEL. — The hand level (Fig. 38) has no telescope, but is simply a metal tube with plain glass

* See Reports of the Superintendent of the U. S. Coast and Geodetic Survey for the year 1898-99, p. 351, and the year 1900, p. 525.

covers at the ends and with a spirit level on top. When looking through the tube one sees the level bubble on one side of the tube in a mirror set at 45° with the line of sight, and the landscape on the other side. In order that the eye may see the bubble and the distant object at the same instant the instrument is focused on the bubble by means of a lens placed in a sliding tube. The level line is marked by a horizontal wire, which can be adjusted by means of two screws. The instrument is held at the eye and the farther end is raised or lowered until the bubble is in the center of the tube. At this instant a point in line with the horizontal wire is noted. In this way approximate levels may be obtained.

LEVELING RODS.

101. According to their construction rods are either *Self-reading* or *Target* rods, or a combination of the two. Self-reading rods are those which can be read directly from the instrument by the levelman whereas target rods can be read only by the rodman. The commonest forms of leveling rods are known as the *Boston*, the *New York*, and the *Philadelphia* rods. (See Fig. 39.)

102. **BOSTON ROD.** — The Boston rod (Fig. 39) is a target rod of well seasoned wood about $6\frac{1}{2}$ ft. long, made in two strips, one of which slides in a groove in the other. A target is fastened rigidly to one of these strips about 0.3 ft. from one end. Clamps are provided for holding the two parts in any desired position. There is a scale on each side of the rod, one starting from either end, graduated to hundredths of a foot and each with a vernier placed about the height of the eye and reading to thousandths of a foot. When the rod-reading is less than 5.8 ft. the rod is first placed on the ground with the target near the bottom. Then the strip carrying the target is raised to the proper height while the bottom of the other strip rests on the ground, as shown in Fig. 39. For readings over 5.8 ft. the rod is turned end for end so that the target is at the top and can be moved from 5.8 to 11.4 ft., the limit of the rod. The terms

Tape Rod.

Self-Reading Rod.

Philadelphia Rod.

New York Rod.

Boston Rod.

FIG. 39. LEVELING RODS.

"*short rod*" and "*long rod*" are used to distinguish these two positions.

The common form of target used on the Boston rod is shown in Fig. 40. Instead of this target one of a design similar to that in Fig. 41 is sometimes used, in which the white strip in the center may be bisected by the horizontal cross-hair. Bisection is more precise under all conditions than setting on a

FIG. 40. BOSTON ROD TARGET.

FIG. 41. BISECTION TARGET.

single line or on the division line between two surfaces of different color.

A serious objection to the Boston rod is that in reversing it (changing from long to short rod) any error in the position of the target with reference to the scale is doubled by the reversal, and such an error is not readily eliminated.

103. NEW YORK ROD.—The New York rod (Fig. 39) consists of two strips of wood, arranged similarly to those of the Boston rod. Unlike the latter the target on the New York rod is **movable**. For "short rod" the target is moved up or down on the rod until the proper height is reached. The face of the rod is graduated to hundredths of a foot. The vernier is on the target itself and reads to thousandths of a foot. The graduations on the rod cannot be read from the instrument except at short distances. For "long rod" the target is set at the highest graduation, usually 6.5 ft., and clamped to one of the sliding strips which is then raised until the target is in the right position. A clamp is provided for holding the two strips together. The reading for "long rod" is found on the side of the strip that is raised, and opposite the vernier which is on the

other strip, the scale reading downward. In this case the rod cannot be read directly from the instrument.

104. PHILADELPHIA ROD. — This rod has the graduations plainly painted on its face so that it can be used as a self-reading rod (Fig. 39). It has a target reading to thousandths, like that of the New York rod. In some cases the target has no vernier but is graduated directly to 0.005 ft.; the thousandths can be readily estimated. The rod is extended in the same manner as the New York rod, and it can be read to 0.005 ft. and estimated to 0.001 ft. by means of a scale fastened on the back of the rod. When the rod is fully extended, the graduations on the front face are continuous and the readings can be made directly by the levelman if desired.

105. SPECIAL SELF-READING RODS. — There are a large number of self-reading rods of special design. One of the commonest types shown in Fig. 39, is similar to the Philadelphia rod except that it has no target and is not graduated closer than tenths. The figures on the face of the rod are made of definite height (0.06 or 0.08 ft.) and of definite thickness (0.01 or 0.02 ft.) so that it is easy for the levelman to estimate the readings to hundredths of a foot. These rods are usually constructed so that they can be extended for "long rod" readings.

106. Tape Rod.* — The tape rod (Fig. 39) is a self-reading rod of decidedly different design from the Philadelphia rod. It is a wooden rod made in one piece with a metal roller set in it near each end. Passing over these rollers is a continuous steel band 20 ft. long and 0.1 ft. wide, on the outside of which for its entire length is painted a scale graduated to feet, tenths, and half-tenths, with the details of the numbers so designed that readings to the nearest 0.01 ft. can readily be made. Unlike the other rods mentioned the scale reads **down** on the face of the rod instead of up. It is provided with a clamp so that the metal band, or tape, can be set at any desired reading and held firmly in that position. The use of this type of rod is limited to cer-

* This rod was invented by Thomas F. Richardson and is used extensively by the Metropolitan Water and Sewerage Board of Boston, Mass.

tain kinds of work, its advantage being the time saved in calculations as explained in Art. 228, p. 206.

107. Precise Level Rod.—The self-reading rod used by the U. S. Coast and Geodetic Survey is made of a single piece of wood, soaked in paraffin to prevent changes in length due to moisture. Metal plugs are inserted at equal distances so that changes in length can be accurately determined. It is divided into centimeters, painted alternately black and white. The bottom of the rod carries a foot-plate. The meters and centimeters are read directly and the millimeters estimated. This rod has attached to it a thermometer, and a level for plumbing.

108. Advantages of the Self-Reading Rod.—While the advantage in the speed with which leveling can be accomplished by use of the self-reading rod is well understood, it is also true

FIG. 42. ROD LEVELS.

although not so generally recognized that very **accurate** results can be obtained. For any single reading the error may be larger than with the target rod, but the errors of estimating fractional parts are **compensating**, so that in the long run the results are found to be very accurate. Precise leveling carried on by the U. S. Coast and Geodetic Survey and by European surveys has demonstrated the superiority of such rods. The

self-reading rod might to advantage be more generally used than it is at present.

109. Attachments to the Rod for Plumbing. — In accurate work it will be convenient to use some device for holding the rod plumb. Spirit levels attached to brass "angles" which may be secured to a corner of the rod are very convenient. Two patterns are shown in Fig. 42. In some rods the levels are set permanently into the rod itself.

110. Effect of Heat and Moisture. — Changes of temperature do not have a serious effect on rods since the coefficient of expansion of wood is small. The effect of moisture is greater, however, and consequently if very accurate leveling is to be done the rod should be compared frequently with a standard. Rods soaked in paraffin are less affected by moisture than those which have not been so treated.

USE OF THE LEVEL AND ROD.

111. In order to obtain the difference in elevation between two points, hold the rod at the first point and, while the instrument is level, take a rod-reading. This is the distance that the bottom of the rod is below the line of sight of the level. Then take a rod-reading on the second point and the difference between the two rod-readings is the difference in elevation of the two points.

112. TO LEVEL THE INSTRUMENT. — Set up the instrument in such a position that the rod can be seen when held on either point and at such height that the horizontal cross-hair will strike somewhere on the rod. In setting up the level, time will be saved if the habit is formed of doing nearly all of the leveling by means of the tripod legs, using the leveling screws only for slight motions of the bubble in bringing it to the middle of the tube. Turn the telescope so that it is directly over two opposite leveling screws. Bring the bubble to the center of the tube **approximately**; then turn the telescope until it is over the other pair of leveling screws and bring the bubble **exactly** to the center. Move the telescope back to the first position and level carefully, and again to the second position if

necessary. If the instrument is in adjustment and is properly leveled in both directions, then the bubble will remain in the center during an entire revolution of the telescope about the vertical axis. The instrument should not be clamped ordinarily, but this may be necessary under some circumstances, for example, in a strong wind.

113. TO TAKE A ROD-READING. — The rodman holds the rod on the first point, taking pains to keep it as nearly plumb as possible. The levelman focuses the telescope on the rod, and brings the bubble to the center **while the telescope is pointing at the rod**, because leveling over both sets of screws will not make the bubble remain in the center in **all** positions unless the adjustment is perfect. If a target rod is used, the target should be set so that the horizontal cross-hair bisects it **while the bubble is in the center of the tube**. It is not sufficient to trust the bubble to remain in the center; it should be examined just before setting the target and immediately afterward, **at every reading**. The levelman signals the rodman to move the target up or down. When the center of the target coincides with the horizontal cross-hair the levelman signals the rodman, "All right" (Art. 115), and the rodman clamps the target and reads the rod. This reading is then recorded in the note-book. In accurate work the levelman should check the position of the target after it has been clamped to make sure that it has not slipped in clamping. For readings to hundredths of a foot it is not necessary to clamp the target; the rodman can hold the two parts of the rod firmly together while he reads it.

While the levelman is sighting the target, the rodman should stand **beside** the rod so that he can hold it as nearly vertical as possible in the direction of the line of sight. The levelman can tell by means of the vertical cross-hair whether it is plumb in the direction at right angles to the line of sight. **It is extremely important that the rod be held plumb.** Vertical lines on buildings are a great aid to the rodman in judging when his rod is plumb. If the wind is not blowing the rodman can tell when the rod is plumb by balancing it on the point.

114. WAVING THE ROD. — In careful work when the "long rod" is used it may be plumbed in the direction of the line of

sight by "*waving the rod.*" To do this the rodman stands directly **behind** the rod and inclines it toward the instrument so that the target will drop below the line of sight. He then **slowly** draws it back, causing the target to rise. It will be highest when the rod is plumb. If at any point the target appears above the cross-hair it should be lowered. If, while the rod is being waved, the target does not reach the cross-hair the target must be raised and the process repeated until as the rod is waved there appears to be just one place where the target coincides with the horizontal line of sight. Whenever close results are desired it will be well to take several readings on each point and use the mean.

115. Signals. — While the rodman is seldom very far away from the levelman in this work still it is often convenient to use hand signals. The following are commonly used in leveling.

"*Up*" or "*Down.*" — The levelman motions to the rodman by raising his arm above his shoulder for an upward motion and dropping his arm below his waist for a downward motion. A slow motion indicates that the target should be moved a considerable amount and a quick motion indicates a short distance.

"*All Right.*" — The levelman extends both hands horizontally and waves them up and down.

"*Plumb the Rod.*" — The hand is extended vertically above the head and moved slowly in the direction it is desired to have the rod plumb.

"*Take a Turning Point.*" — The arm is swung slowly in a circle above the head.

"*Pick up the Level.*" — When a new set-up of the level is desired the chief of party signals the levelman by extending both arms downward and outward and then raising them quickly.

Some surveyors use a system of signals for communicating the rod-readings, but mistakes are liable to be made unless great care is used.

116. DIFFERENTIAL LEVELING. — Differential leveling is the name given to the process of finding the difference in elevation of any two points. In Art. 111 the simplest case of differential leveling is described. When the points are far apart the instrument is set up and a rod-reading is taken on the first point.

This is called a *backsight* or *plus sight* and is usually written *B. S.* or $+ S.$ Next the rod is taken to some well-defined point which will not change in elevation (such as the top of a firm rock) and a reading taken. This is called a *foresight* or *minus sight* and is written *F. S.* or $- S.$ The difference between the two readings gives the difference in elevation between this new point and the first point. This second point is called a *turning point* and is written *T. P.* The level is next set up in a new position and a backsight taken on the turning point. A

FIG. 43. DIAGRAM ILLUSTRATING DIFFERENTIAL LEVELING.

new turning point is then selected and a foresight taken upon it. This process is continued until the foresight is taken on the final point. The elevation of the last point above the first is equal to the sum of all the backsights minus the sum of all the foresights. If the result is **negative**, i.e., if the sum of the foresights is the **greater**, then the last point is **below** the first. The form of notes for this work is shown below, and the fieldwork is illustrated by Fig. 43.

	14.487		

Diff. 19.025 B above A.

117. The Proper Length of Sight.—The proper length of sight will depend upon the distance at which the rod appears distinct and steady to the levelman, upon the variations in readings taken on the same point, and upon the degree of precision required. Under ordinary conditions the length of sight should not exceed about 300 ft. where elevations to the nearest 0.01 ft. are desired. "Boiling" of the air due to irregular refraction is frequently so troublesome that longsights cannot be taken accurately.

If the level is out of adjustment the resulting error in the rod-reading is proportional to the distance from the instrument to the rod. If the level is at equal distances from the rod the errors are equal and since it is the **difference** of the rod-readings that gives the difference in elevation, the error is eliminated from the final result if the rodman makes the **distance to the point where the foresight is taken equal to the distance to the backsight** by counting his paces as he goes from one point to the other.

118. Effect of the Earth's Curvature and of Refraction on Leveling.—Since the surface of the earth is very nearly spherical,

FIG. 44. DIAGRAM ILLUSTRATING EFFECT OF EARTH'S CURVATURE AND OF REFRACTION.

any line on it made by the intersection of a vertical plane with the earth's surface is practically circular. In Fig. 44 the distance AA' varies nearly as $A'L^2$ (see foot-note, p. 339). The effect of

the refraction of the atmosphere is to make this offset from the tangent appear to be $A'B$ which is about one-seventh part smaller than $A'A$. This offset, corrected for refraction, is about 0.57 ft. in one mile; for 300 ft. it is 0.002 ft.; for 500 ft., 0.005 ft.; for 1000 ft., 0.020 ft. If the rod is equally distant from the instrument on the foresight and backsight the effect of curvature and refraction is eliminated from the result.

119. PRECAUTIONS IN LEVEL WORK. — Nearly all of the precautions mentioned in Art. 68, p. 55, for the transit instrument, are also applicable to the level. Care should be taken not to strike the rod on the ground after it has been clamped and before it has been read.

ADJUSTMENTS OF THE LEVEL.

I. ADJUSTMENTS OF THE WYE LEVEL.

120. ADJUSTMENT OF THE CROSS-HAIRS. — (a) **To make the Horizontal Cross-Hair truly Horizontal when the Instrument is Leveled.** This may be done by rotating the cross-hair ring as in the case of the transit (Art. 71, p. 57), if the instrument is so constructed that the telescope cannot be rotated in the wyes. In many instruments the telescope can be rotated in the wyes. In some levels the telescope is always free to rotate in the wyes, while others are provided with a stop regulated by an adjusting screw, which prevents the telescope from rotating beyond a certain point.

The instrument is leveled and some point found which is covered by the horizontal cross-hair. The telescope is turned slowly about the vertical axis so that the point appears to traverse the field of view. If the point remains on the cross-hair the adjustment is perfect. If it does not, then an adjustment must be made, the manner of doing this depending upon the construction of the instrument. If the telescope cannot be rotated in the wyes the adjustment is made by rotating the cross-hair ring, similar to the adjustment described in Art. 71, p. 57. If the telescope has a stop-screw this must be moved until the instrument

satisfies this test. If the telescope can rotate freely in the wyes it can be turned by hand until it satisfies the test. Since there is nothing to hold the telescope in this position the adjustment in the last case is likely to be disturbed at any time.

121. (b) When the above adjustment is completed the **Line of Sight should be made to Coincide with the Axis of Pivots, or Parallel to it.** (See Fig. 45.) Pull out the pins which hold the clips on the telescope and turn the clips back so that the telescope is free to turn in the wyes. Sight the intersection of the cross-hairs at some well-defined point, using the leveling screws for the vertical motion and the clamp and tangent screw for the horizontal motion. Then rotate the telescope 180° in the wyes, so that the level tube is above the telescope. The intersection of the cross-hairs should still be on the point. If not, move the horizontal cross-hair half-way back to its first position by means of the upper and lower adjusting screws of the cross-hair ring. Then move the vertical cross-hair half-way back to its first position by the other pair of screws. Repeat the test until the adjustment is perfect.

FIG. 45. ADJUSTMENT OF THE CROSS-HAIRS (SECOND PART).

122. **ADJUSTMENT OF THE LEVEL TUBE.**—To make the **Line of Sight and the Level Tube Parallel to Each Other.** Two methods are used,—the *direct*, or “*peg*,” method and the *indirect* method. While the former is the only one applicable to the dumpy level either one can be used for the wye level, although the indirect method is the simpler.

123. **ADJUSTMENT OF THE LEVEL TUBE BY INDIRECT METHOD.**—(a) To put the **Axis of the Bubble Tube in the Same Plane with the Line of Sight.** Bring the bubble to the center of the tube and rotate the telescope in the wyes for a few degrees (very little is necessary); if the bubble moves toward one end of the tube that end must be the higher, which indicates the direction in which the adjustment should be made. Move

the screws controlling the lateral movement of the tube until the bubble returns to the center. Test the adjustment by rotating the telescope each way.

124. (b) **To make the Axis of the Bubble Tube and the Line of Sight Parallel to Each Other.** First clamp the instrument (over a pair of leveling screws), then bring the bubble to the center of the tube, lift the telescope out of the wyes, turn it end for end and set it down in the wyes, the eye end now being where the objective was originally. (See Fig. 46.) This operation must be performed with the greatest care, as the slightest jar of the instrument will vitiate the result. If the bubble returns to the center of the tube, the axis of the tube is in the correct position. If it does not return to the center, the end of the tube provided

FIG. 46. ADJUSTMENT OF THE BUBBLE TUBE BY INDIRECT METHOD.

with the vertical adjustment should be moved until the bubble moves half-way back to the center. This test must be repeated to make sure that the movement is due to defective adjustment and not to the jarring of the instrument.

125. **ADJUSTMENT OF THE WYES.** — To make the Axis of

FIG. 47. ADJUSTMENT OF THE WYES.

the Level Tube Perpendicular to the Vertical Axis of the Instrument. Bring the two clips down over the telescope and fasten them. Level the instrument, bring the bubble precisely to the middle of the tube over one set of leveling screws, and then turn the telescope 180° about the vertical axis. If the bubble moves from the center bring it half-way back by means of the adjusting screws at the foot of one of the wye supports. (See Fig. 47.)

Since the bubble is brought to the center of the tube each time a rod-reading is taken this last adjustment in no way affects the accuracy of the leveling work but is a convenience and a saving of time.

11. ADJUSTMENTS OF THE DUMPY LEVEL.

126. ADJUSTMENT OF THE CROSS-HAIR. — If the horizontal cross-hair is not truly horizontal when the instrument is level it should be made so by rotating the cross hair ring as described in the adjustment of the transit, Art. 71, p. 57.

127. ADJUSTMENT OF THE BUBBLE TUBE. — **To make the Axis of the Bubble Tube Perpendicular to the Vertical Axis.** Owing to the construction of the dumpy level it is necessary to make this adjustment **before** making the line of sight parallel to the bubble tube. It is done by centering the bubble over one pair of leveling screws, and turning the instrument 180° about the vertical axis. If the bubble does not remain in the center of the tube, move it half-way back to the center by means of the adjusting screws on the level tube.

128. THE DIRECT, OR "PEG," ADJUSTMENT. — **To make the Line of Sight Parallel to the Axis of the Bubble.** (See Fig. 48.) Select two points *A* and *B*, say, 200 ft. or more apart. Set up the level close to *A* so that when a rod is held upon it the eye-piece will be only about a quarter of an inch from the rod. Look through the telescope **wrong end to** at the rod and find the reading opposite the center of the field. After a little experience it will be found that this can be done very accurately. From the fact that only a small portion of the rod is visible it will be found convenient to set a pencil-point on the rod at the center of

the small field of view. Turn the telescope toward *B* and take a rod-reading on it in the usual way, being certain that the bubble is in the middle of the tube. The difference between these two rod-readings is the difference of elevation of the two points **plus** or **minus** the error of adjustment. The level is next taken to *B* and the above operation is repeated. The result is the difference in elevation **minus** or **plus** the same error of adjustment. The mean of the two results is the true difference in elevation of points *A* and *B*. Knowing the difference in elevation between the two points and the height of the instrument above *B* the rod-reading at *A* which will bring the target on the same level as the instrument may be computed. The bubble is brought to the center of the tube and the horizontal cross-hair raised or lowered by means of the adjusting screws on the cross-hair ring until the line of sight strikes the target. In this method the small error due to curvature of the earth (nearly 0.001 ft. for a 200-ft. sight) has been neglected.

EXAMPLE.

(See Fig. 48.)

Instrument at A.

Rod-reading on A = 4.062

Rod-reading on B = 5.129

Diff. in elev. of A and B = 1.067

Instrument at B.

Rod-reading on B = 5.076

Rod-reading on A = 4.127

Diff. in elev. of B and A = 0.949

Mean of two diff. in elev. = $\frac{1.067 + 0.949}{2} = 1.008$ true diff. in elev.

Instrument is now 5.076 above B.

Rod-reading at A should be $5.076 - 1.008 = 4.068$ to give a level sight.

The peg method may be used for adjusting the wye level or the transit, the difference being that in the dumpy level the axis of the bubble tube is first made horizontal and then the line of sight is brought parallel to it, while in the wye level and in the transit the line of sight is first made horizontal and then the axis of the bubble tube is made parallel to it. Consequently, in the former case the cross-hair ring is moved in adjusting whereas in the latter case the adjustment is made in the bubble tube. This

adjustment in its simplest form is described in the following article.

FIG. 48. PEG ADJUSTMENT.

129. ADJUSTMENT OF THE LOCKE HAND LEVEL. — In adjusting the hand level the principle of the peg adjustment is used. The level is placed at a mark *A* (Fig. 49) and another mark *B* in line with the cross-hair is made, say, 100 ft. away,

FIG. 49. PEG ADJUSTMENT FOR HAND LEVEL.

when the bubble is in the middle. The level is then taken to *B*, held so that its center is at the height of this mark, and sighted toward the first point. A third point *C* is marked in

line with the cross-hair when the bubble is in the middle. The point midway between *A* and *C* is at the same level as *B*. The adjustment is made by screws which move the horizontal wire.

130. COMMON SOURCES OF ERROR IN LEVELING. —

1. Improper focusing (parallax).
2. Bubble not in middle of tube at instant of sighting.
3. Rod not held plumb.
4. Foresights and corresponding backsights on turning points not equally distant from the instrument.
5. Poor turning points selected. (See Art. 224, p. 202.)

131. COMMON MISTAKES. —

1. Foresight and Backsight not taken on exactly the same point.
2. Neglecting to set target accurately when "long rod" is used.
3. In the use of the self-reading rod neglecting to clamp the rod at the proper place when "long rod" is used.
4. Reading the wrong foot-mark or tenth-mark.
5. In keeping notes, — getting F. S. in B. S. column or *vice versa*.
6. In working up notes, adding F. S. or subtracting B. S.

PROBLEMS.

1. A wye level was tested for the sensitiveness of the bubble, as follows: the rod was held on a point 200 ft. away; the bubble was moved over 13.6 divisions of the scale; the rod-readings at the two extreme positions of the bubble were 4.360 and 4.578. Compute the average angular value of one division of the level.

2. A dumpy level was tested by the peg method with the following results.

Instrument at *A* : —

+ S. on *A*, 4.139
— S. on *B*, 4.589

Instrument at *B* : —

+ S. on *B*, 3.900
— S. on *A*, 3.250

Find the rod-reading on *A* to give a level line of sight, the instrument remaining 3.900 above *B*. Was the line of sight inclined upward or downward? How much?

3. The target on a Boston rod has been disturbed and it is desired to find out if the target is in the correct position with reference to the scale. Describe a method by which the amount of this error can be determined.

4. A New York rod is found to be 0.002 ft. short, due to wear on the brass foot-plate. Explain what effect this will have in finding the difference in elevation between two points.

5. (a). A level is set up and a + S. of 5.098 is taken on a point 400 ft. away, then a - S. of 3.260 is taken on a point 900 ft. away. What is the curvature and refraction correction? What is the difference in elevation of the two points?

(b). In another case a + S. of 8.26 was taken on a point 100 ft. away and a - S. of 6.405 taken on a point 600 ft. away. What is the curvature and refraction correction? What is the difference in elevation of the two points?

PART II.
SURVEYING METHODS.

PART II.

SURVEYING METHODS.

CHAPTER V.

LAND SURVEYING.

✓ 132. **SURVEYING FOR AREA.**—In surveying a field for the purpose of finding its area the instruments and methods used will be determined largely by the degree of accuracy required. If it is permissible to have an error in the area of, say, 0.5 per cent then the compass and chain may be used. If accuracy much greater than this is required it will be necessary to use the transit and the steel tape. At the present time, however, in nearly all work except surveys of farms and woodlands, the transit is used even under conditions where the compass would give the required accuracy.

In surveying a field all the angles and lengths of the sides are determined consecutively, the survey ending at the point from which it was started. Then by trigonometry the position of the *final* point or of any other point with relation to the starting point can be readily calculated. If the survey were absolutely accurate the last point as calculated would coincide with the first, but this condition is never attained in practice. The calculated distance between the two, divided by the perimeter of the field, is usually called the *error of closure*; * it is often expressed in the form of a fraction in which the numerator is unity. In surveying with a compass and chain the error of closure expected is about 1 part in 500, expressed as $\frac{1}{500}$.

133. **SURVEYING FOR AREA WITH COMPASS AND CHAIN.**—If the area alone is desired the surveyor's 4-rod chain will be

* The term *error of closure* more properly applies to the actual distance by which the survey fails to close, but as this is generally expressed in the form of a fraction the term has commonly been applied to the latter.

convenient on account of the simple relation existing between the square chain and the acre (Art. 4, p. 3). In making a survey enclosing an area it is customary to begin at some convenient corner and to take the bearings and the distances in order around the field. As the measurements are made they are recorded in a field note-book. It is not **necessary** to take the sides in order, but since they must be arranged in order for the purpose of computing the area it will be **convenient** to have them so arranged in the original notes. If the length and bearing of any side are omitted the area is nevertheless completely determined (Art. 397, p. 366), but as these two measurements furnish a valuable check on the accuracy of all the measurements

FIG. 50. NOTES OF CHAIN AND COMPASS SURVEY.

they **never** should be omitted if they can be taken. It is of the utmost importance in every survey that check measurements should be taken. Even a few rough checks taken in the field which will require only a little extra time often prove to be of great value in detecting mistakes. Both a forward bearing and a back (or reversed) bearing should be taken at each corner; from these the angle at a corner can be obtained free from error due to any local attraction of the needle. The above process gives a series of connected straight lines and their bearings (or the angles between them), which is called a *traverse*.

It is often impossible to set the compass up at the corners of the property, and in such cases assumed lines running parallel or approximately parallel to the property lines can be

surveyed as described in Art. 134, and the area determined. In some cases the compass can be set on the property line at an intermediate point and the bearing obtained, but the surveyor must be sure that there is no local attraction of the needle at this point. All points where the compass is set should be marked and described so that they can be found again. If any instrument point is not otherwise defined it may be temporarily marked by a small stake and several reference measurements made from this stake to prominent objects nearby, so that its position can be relocated if the stake is lost. These measurements are called *ties*.

Notes of the traverse are usually recorded as shown in Fig. 50.

SURVEY OF FIELD WITH TRANSIT AND TAPE.

134. SURVEY OF A FIELD BY A TRAVERSE. — Surveying a field for area can usually be done in one of the three following ways.

(1). By setting up the transit at the corners of the property and measuring the angles directly ; the distances being measured directly along the property lines.

(2). When the property lines are so occupied by buildings or fences that the transit cannot be set up at the corners, but the distances can still be measured along the property lines, then the angles at the corners are obtained by measuring the angles between lines which are parallel to the property lines.

(3). If the boundaries of the property are such that it is not practicable to set the transit up at the corners nor to measure the distance directly on the property lines, a traverse is run approximately parallel to the property lines and these lines connected with the traverse by means of angles and distances.

135. In case (2) the parallel lines are established in the following manner. Set the transit up at some point *E*

(Fig. 51) within 2 or 3 ft. of the corner A . Establish the line EF parallel to AD by making $DF = AH$ by trial. Point H cannot be seen through the telescope, but it is so near the instrument that by means of the plumb-line on the transit it can be accurately sighted in by eye. Similarly EG is established parallel to AB . Then the angle FEG is measured ; and this is the property

FIG. 51. TRANSIT LINES PARALLEL TO THE SIDES OF FIELD.

angle at A . It is evident that the values of AH and DF and of AI and BG are of no permanent use and are therefore not recorded in the notes. When practicable it is advisable to choose the transit point, K for example, on one of the property lines or its prolongation. Fig. 52 is a set of notes illustrating either case (1) or (2).

136. In case (3) the transit can be set up at an arbitrary point marked by a stake and chosen far enough from one of the corners so that the telescope can be focused on it. In this way all the corners of the traverse are chosen so that the traverse will be approximately parallel to the sides of the field. The angles and distances of this traverse are then measured. To connect the property lines with this traverse, angles and distances are measured to the respective corners of the property before the instrument is moved to the next point. Fig. 53 is a set of notes illustrating this case. Time can be saved in the computations and a good check on the work may be obtained if the property lines are also measured when possible. These are not only useful as checks on the accuracy of the survey, but the

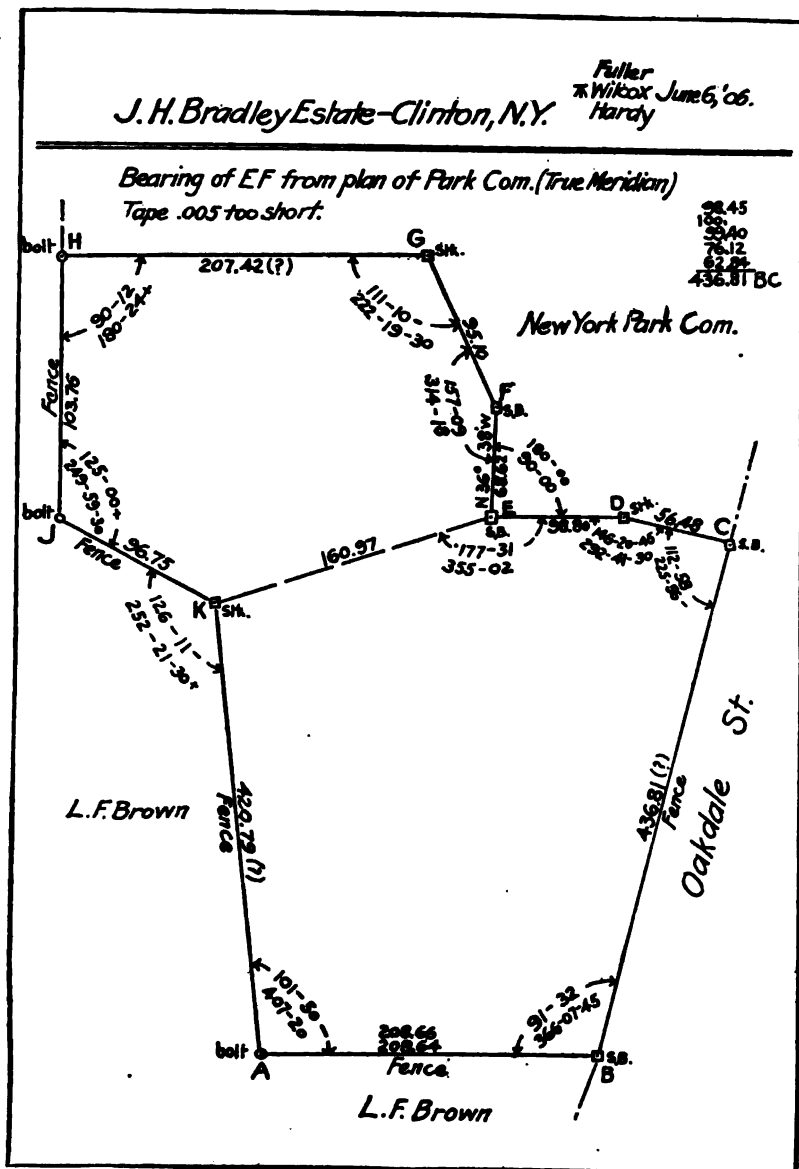

FIG. 52. NOTES OF SURVEY WITH TRANSIT AND TAPE.

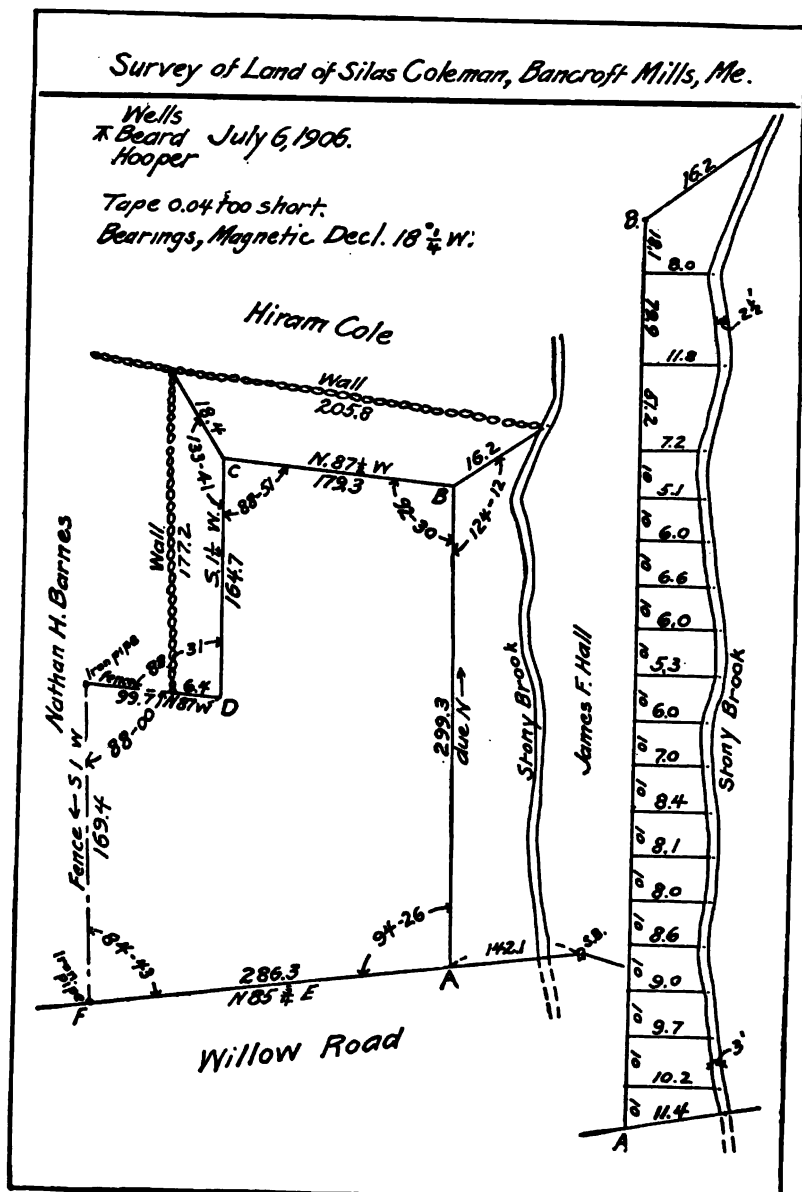

FIG. 53. NOTES OF SURVEY WITH TRANSIT AND TAPE.

length of the sides will be needed in giving a description of the property.

These three methods which have been described may be combined in any survey according to circumstances.

137. Irregular Curved Boundaries. — When a tract of land is bounded by an irregular curved line such as a brook it is customary to run the traverse line near it, sometimes crossing it several times, and to take perpendicular offsets to the brook. If it is a winding brook with no distinct turns in it, offsets at regular intervals are measured from the transit line as in the portion near point *A* of Fig. 53. Near point *B* in this figure the brook has practically a direct course between its turns, in which case the proper measurements to make are the offsets to those points where the course of the brook changes and the distances along the transit line between these offset lines. Since they are usually short the right-angle offset lines are laid off by eye.

138. SURVEY OF A FIELD BY A SINGLE SET-UP OF THE TRANSIT. — When it is necessary to economize time in the field at the expense of accuracy and of the time required to calculate the survey the following method may be used. If possible set up at a point within the field, preferably near the middle, from which all the corners can be seen, and measure the angles and distances to each corner. In this way the field is divided into several oblique triangles in each of which two sides and the included angle have been measured and from these the area and third side (property line) can be computed. As a check on the measured angles their sum should be 360° ; there is no check on the property lines unless they are measured directly.

This method of surveying a field may be employed as a check on one of the other methods which have already been described, but is not recommended as a method to be used by itself except in emergencies. The weak point in it is the low degree of precision with which the angles are usually measured. Here the effect of an error of, say, 30 seconds in an angle may often be much larger than the errors in the measured distances (Art. 352, p. 325). The additional measurement of the property line gives the length of all three sides of the various triangles into which

the field is divided. If the area is calculated from the three sides of the triangles, using the measured angles as checks only, an accurate result may be obtained, but at the expense of considerable office work.

139. SURVEY OF A FIELD WITH A TAPE ONLY. — Sometimes it may be necessary to survey a field when a transit is not at hand. This can be done by dividing the field into several triangles and measuring all their sides. To insure accuracy of results the triangles should be so chosen that there are no angles in them less than 30° or greater than 150° . This method will require a large amount of computation if the angles as well as the area of the field are desired. Lining in by eye will give accurate results in distances along the line, but only approximate side measurements can be obtained from such a line.

140. SELECTING THE CORNERS. — If a corner is marked by a stone bound the exact point may be easily found; but where it is simply defined as the intersection of stone walls or fences the surveyor will have to examine all evidence as to its position and use his judgment in deciding where the true corner is located (Art. 151, p. 116). When the property is bounded by a public way or a town boundary such data relating to the location of these lines must be obtained from the proper local authorities. After determining the position of the corner points, the surveyor should use precisely the same points in all distance or angle measurements. If stakes are used the exact point is marked by a small tack driven into the top of the stake.

In deciding upon the location of the boundary lines from an examination of artificial features it should be borne in mind that it is customary to build fences or walls along highways entirely on private property so that the face of the wall or fence is on the side line of the highway. In cities the base-board of a fence is usually built so that its face is on the street line, but the location of the fences has no weight when the street line is defined by stone bounds or other permanent marks (Art. 253, p. 227). For boundaries between private lands the legal line is, in the case of a stream, the thread (not necessarily the center) of the stream; the center of the stone wall or Virginia rail fence; the line between the bottom stringer and the boarding or pickets of an

ordinary fence, the fence-posts being entirely on one side of the boundary line. Not infrequently woodland is marked off by blazing the trees on one or both sides of the boundary line, the blazing being done on the side of the tree nearest the boundary line. If a tree comes directly on the line it is blazed on both sides where the line strikes it. A small pile of stones, sometimes with a stake in the center of the pile, is often used to mark the corners of such land.

141. METHOD OF PROCEDURE.— In deciding where the traverse shall be run the surveyor should keep in mind both convenience in fieldwork and economy in office work. Frequently a method of procedure which shortens the time spent in the field will greatly increase the amount of labor in the office. Circumstances will determine which method should be used. If there is no special reason why the time in the field should be shortened, the best arrangement of the traverse will be the one that will make the computation simple, and hence mistakes will be less liable to occur. If the lines of the traverse coincide with the boundary, as in cases (1) and (2), the amount of office work will be the least. If in case (3) the traverse lines are approximately parallel and near to the boundaries of the property the computation of the small areas to be added to or subtracted from the area enclosed by the traverse is simplified to some extent.

142. TIES.— All important points temporarily marked by stakes should be "tied in," i.e., measurements should be so taken that the point may be readily found or replaced in the future. There should be at least three horizontal ties which intersect at angles not less than 30° . They should be taken from easily recognized definite points, such as blazed trees, stone bounds, fence posts, or buildings. All such measurements should be carefully recorded, usually by means of a sketch. Fig. 54 shows a stake located by ties measured to tenths of a foot ; these are taken

FIG. 54. APPROXIMATE TIES.

but if neither is known any arbitrary direction may be assumed. The upper clamp is loosened and the telescope sighted on *B*. The angle read on the vernier is the azimuth of *AB*, the circle being read in a clockwise direction (Art. 24, p. 16). The transit is next moved to *B*.

The azimuth of *BC* may be obtained in one of two ways. (1) Invert the telescope and backsight on *A*, the vernier remaining at the reading it had at *A*; then clamp the lower plate, turn the telescope to its direct position, and sight on *C*. The angle on the vernier is the azimuth of *BC* referred to the same meridian as the azimuth of *AB*. The disadvantage of this method is that the error of collimation enters the azimuth angle each time. (2) Add 180° to the azimuth of *AB*, set this off on the vernier, and sight on *A*. The telescope may then be turned directly to *C* (without inverting) and the azimuth of *BC* can be read directly on the vernier. The disadvantages of this method as compared with the former are that the error of eccentricity of the circle enters, that time is consumed in setting the vernier at each set-up of the instrument, and that there is an opportunity for mistakes in calculating and in making the setting on the vernier.

FIG. 56. AZIMUTH ANGLES.

In the azimuth method the angles of the traverse are checked by the fieldwork. After point *D* has been occupied, the transit is again set up at *A* and the azimuth of *AB* determined from a backsight on *D*. This azimuth of *AB* should agree with the original azimuth of this line. In ordinary land surveying the azimuth method of measuring the angles is little used.

145. Checking the Fieldwork. — The transit is set over the selected points and the angles between the adjacent lines measured. If the work is not to be of unusual precision a

transit reading to one minute will be sufficient. A single measurement will give the angle with sufficient precision, but as it is important in all cases to have a check on the work it is advisable to "double the angle" (Art. 60, p. 50), even though it is not necessary to use this method for the purpose of precision. Referring to Fig. 52, p. 103, it will be seen that the angles were quadrupled where the sides were long, and doubled where they were short. In this case the angles were repeated to obtain greater precision.

As an additional check against large errors in the angles, the magnetic bearing of each line should be read, thus enabling one to detect mistakes greater than a quarter of a degree and to guard against reading Right for Left in deflection angles. These bearings also show the approximate directions of the lines of the survey. This check should always be applied **in the field** so that any mistake in reading the angles can be rectified before leaving the work. This may be done by calculating each angle from the **observed bearings** of the adjacent sides; or by starting with one observed bearing (assumed to be correct), calculating the other bearings in succession by means of the measured angles, and noting whether the observed bearings agree approximately with the *calculated bearings*.

After the angles have been measured, the accuracy of the transit work may be tested by adding them together. The sum of the interior angles of the field should equal $(n-2) \times 180^\circ$, where n is the number of sides in the field. If the deflection angles are used the sum of all the right deflections should differ from the sum of all the left deflections by 360° , or in other words, **the algebraic sum of the deflection angles should be 360°** .

It is frequently important to check the distances before leaving the field. If there is any doubt as regards the correctness of the measurement of a line it should be remeasured, preferably in the **opposite direction**, so that the same mistake will not be repeated. (See line *AB* in Fig. 52, p. 103.) If the traverse lines do not coincide with the boundaries, an independent check is obtained by measuring along the boundaries as well as on the traverse line, as in Fig. 53, p. 104. This furnishes at once a

rough check on the distances in the field and a **close** check after the survey has been calculated. It is often advisable to run a line across the traverse, especially when there are many sides to the field, thus dividing the field into two parts, as in Fig. 52, p. 103. If any mistake has been made it is then possible to tell in which portion of the traverse it occurred (Art. 407, p. 371).

146. ACCURACY REQUIRED. — In order that the accuracy in the measurement of distances shall be consistent with that of the angles it is necessary that great care should be exercised in holding the tape horizontal, in the plumbing, in the aligning, and in securing the proper tension.

If the angles are measured to the nearest minute and the distances to the nearest tenth of a foot, it will be sufficiently accurate to use sighting-rods in "giving line." The error of closure of such a survey should be not greater than $\frac{1}{8000}$, but would seldom be less than $\frac{1}{10000}$ (Art. 132, p. 99).

If the property is very valuable, as in the case of city building lots, it is well to use a transit reading to 30" or 20". The angles should be repeated, not only as a check against mistakes, but to increase the precision of the measurement (Art. 59, p. 48). The tape measurements should be made with special care, and should be taken to the nearest hundredth of a foot. In the best work the temperature correction should be applied, a spring balance should be used to give the right pull on the tape, the correction to the standard distance should be determined (Art. 241, p. 216), the alignment given with the transit, and great care taken in plumbing. Sights are given by holding a pencil vertically on top of the tack on the stake or by plumb-line (Art. 65, p. 52). In this work it is important that the property line should be followed, when possible, to insure the most accurate results. In such work an error of closure of $\frac{1}{40000}$ or better is expected. It is customary on most city work to neglect the effect of temperature and to omit the use of the spring balance, the pull being carefully judged. This sort of work should give results as close as $\frac{1}{20000}$, and an accuracy of $\frac{1}{40000}$ is sometimes reached.

147. ORGANIZATION OF TRANSIT PARTY. — Transit surveys can be readily carried on by a party of three men. The note

keeper who is in charge of the party directs the entire work ; the transit-man who has the instrument always in his care sets it up where directed by the note keeper, reads the angles and gives line when desired ; the chainman generally acting as head-chainman and the note keeper as rear-chainman, measure all distances.

148. NOTE KEEPING.— All measurements should be recorded in a special note-book **as soon as they are made** and never left to be filled in from memory. **The notes should be neat and in clear form so that there will be no doubt as to their meaning.** Great care should be taken so that they shall not be susceptible of any interpretation except the right one. They are generally recorded in pencil, but they should always be regarded as permanent records and not as temporary memoranda. As other persons who are not familiar with the locality will probably use the notes and will depend entirely on what is recorded, it is very important that the notes should contain all necessary data without any superfluous information. If the note keeper will bear in mind constantly how the survey is to be calculated or plotted it will aid him greatly in judging which measurements must be taken and which ones are unnecessary. Clearness is of utmost importance in note keeping, and to attain it the usual custom is not to attempt to sketch to scale ; and yet in surveys where considerable detail is desired it is sometimes well to carry out the sketches in the note-book approximately to scale. Care should be taken not to crowd the notes,— paper is cheap,— and an extra page of the note-book devoted to a survey may save hours of time in the office consumed in trying to interpret a page of crowded data. Too much stress cannot be laid on the importance of being careful not to lose the note-book ; not infrequently a note-book contains data which thousands of dollars could not replace.

Although sufficient fulness to make the notes clear is desirable, it is customary to abbreviate the names of the artificial features most commonly met with by the surveyor. To properly understand a set of notes one must be familiar with these abbreviations, some of the more common of which are enumerated.

S.B.	Stone bound.
Mon.	Monument.
△	Triangulation Station.
Stk.	Stake.
tk	Tack.
na.	Nail.
Spt.	Spike.
dh.	Drill-hole.
c.f.	Crow-foot (a mark like this ∇ or ψ).
c.c.f.	Cut crow-foot (cut into wood or stone).
c.	Center.
cl	Center line.
cb	Curb.
C.B.	Catch basin.
M.H.	Manhole.
tel	Telegraph pole.
— · — · —	Fence.
	Fence, showing on which side the posts are.
bb.	Base-board of fence.
	Line of building; the outside line is the base-board, the cross-hatched part is the line of the stone or brick underpinning.

Distances should always be recorded in such a way as to indicate the precision with which they were taken. For example, if they were taken to hundredths of a foot and a measurement happened to be just 124 ft. it should be recorded as 124.00, not as 124. The two zeros are of as much consequence as any other two digits which might have come in their places. Angles which have been read to the nearest half-minute, however, are recorded as follows: $6^{\circ} 47' 30''$. It will be seen that this is not consistent with the foregoing. A more

proper way of reading this angle would be $6^{\circ} 47\frac{1}{2}'$, but this is not common practice.

In addition to the measurements every set of notes should contain the following information:—the kind of work, the locality, the date, and the names of members of the field party. It is well to also state the names or numbers of the instruments used and their errors. Where a survey is continued for several pages the date may be placed at the top of every page; other data need not be repeated. Fig. 50, p. 100, Fig. 52, p. 103, and Fig. 53, p. 104, are good examples of field notes.

149. SURVEY OF A FIELD FOR A DEED.—In this case the lengths and bearings of all the boundaries are desired. The traverse lines should therefore follow the property lines, if possible. The bearings desired are not the observed magnetic bearings, but are those calculated by means of the transit angles as explained in Art. 145, p. 109, and therefore are relatively as accurate as the angles themselves. In case a true meridian is found by observation (Chapter VII) the bearings should be referred to this and marked **true bearings** by a note on the plan, and this information should also be contained in the deed.

A plan which is to accompany a deed should show such features as watercourses, highways, buildings, and adjoining property lines, as well as stone bounds, stakes, fences, walls, or other artificial objects which mark the boundaries of the property.

This plan should contain the following information.

- (1) Lengths of all property lines together with their calculated bearings or the angles at the corners.*
- (2) Location and description of corner bounds.
- (3) Conventional sign or name on walls, fences, etc.

* It is customary with many surveyors to omit from the plan certain data such as the angles or bearings, so that, while it may answer the purpose for which it was made, it does not contain all the data and frequently not enough to enable another surveyor to relocate the property by means of it. This is done, of course, so that when the tract is to be resurveyed or plotted it will be necessary to employ the same surveyor who has in his possession data for which the owner has paid and which the surveyor should have turned over to him. For a valuable paper on this subject see "The Ownership of Surveys, and what Constitutes a Survey and Map," by Professor William G. Raymond, published in *The Polytechnic*, the student journal of the Rensselaer Polytechnic Institute, Troy, N. Y., January, 1894.

(4) Names of highways, streams or ponds, and names of adjacent property owners.

(5) Scale of drawing and direction of the meridian used (true or magnetic). It is better to refer all bearings to the true meridian when possible, and in such a case the direction of the magnetic needle should also be shown.*

(6) The title should include a simple and complete statement giving the name of owner, place, date, and name of surveyor. An explanatory note such as a statement as to whether bearings refer to true or magnetic meridian may also be necessary. (See Art. 468, p. 415.)

150. Deed Description. — The written description of the property which is recorded in the deed should be given by bearings (or angles) and distances, stating in every case how the sides of the property are marked and whether bounded by a highway, stream, or private property, giving the name of the present owner of the adjacent property. The following is an example of a deed description of the property shown in the form of notes in Fig. 53, p. 104.

“Beginning at a point in the northerly line of Willow Road in the town of Bancroft Mills, Maine, at an iron pipe sunk in the ground at the S.E. corner of land now or formerly belonging to Nathan H. Barnes, and running along the said northerly line N 85° 34' E a distance of two hundred ninety-seven and seven-tenths (297.7) feet to the thread of channel of Stony Brook at land now or formerly belonging to James F. Hall; thence turning and running in a northerly direction, by thread of channel of said Stony Brook and land of said Hall, a distance of about three hundred and eight (308±) feet to a stone wall at land now or formerly belonging to Hiram Cole; thence turning and running along the middle of said stone wall and by land of said Cole

* As magnetic bearings are unreliable (Art. 28, p. 19) true bearings should be used wherever their adoption does not entail too much additional expense. In those parts of the country which have been subdivided by the U. S. General Land Office true meridians can be readily obtained from the government surveys; in many of the older (Eastern) states true meridians have been established by local authorities. If the survey can be connected with any triangulation system such as that of the United States or state surveys then, since the true bearings of all of the triangulation lines are known, the bearings of the traverse lines can be obtained.

N $86^{\circ} 45'$ W a distance of two hundred and five and eight-tenths (205.8) feet to the middle of another stone wall at land of said Barnes; thence turning and running by latter stone wall and land of said Barnes S $0^{\circ} 53'$ E a distance of one hundred and seventy-seven and two-tenths (177.2) feet to a fence; thence turning and running by said fence and land of said Barnes N $87^{\circ} 09'$ W a distance of ninety-three and three-tenths (93.3) feet to an iron pipe sunk in the ground; thence turning and running by a fence and land of said Barnes S $1^{\circ} 51'$ W a distance of one hundred and sixty-nine and four-tenths (169.4) feet to the point of beginning; all the bearings being magnetic and the parcel containing a calculated area of 79,305 square feet more or less."

It is unfortunate that the description of the property in deeds in the vast majority of cases, does not define the property in such a manner that it can be plotted from the description. Some deeds are so loosely written as to contain only the names of the owners of adjacent property, no bearings or distances being given.

151. JUDICIAL FUNCTIONS OF THE SURVEYOR.— In rerunning old property lines which have been obliterated, the surveyor is called upon to set aside temporarily his strict adherence to the mathematical side of surveying and must endeavor to find if possible **where the lines originally ran**. He should therefore be familiar with the relative importance of various evidence regarding the location of the property lines, as determined by court decisions. It is distinctly his duty to **find the position of the original boundaries** of the property and **not attempt to correct the original survey** even though he may be sure that an error exists in it. Very often it is true that, owing to the cheapness of land, the original survey was roughly made with little thought of the effect it would have when the land became valuable.

The surveyor therefore must first of all hunt for all physical evidence of the location of the boundaries * and failing in this he

* It must not be assumed that a boundary is missing because it is not at once visible. Stone bounds are often buried two or three feet deep; the top of a stake soon rots off, but evidences of the existence of the stake are often found many years after the top has disappeared, and the supposed location should be carefully dug over to find traces of the old stake. The shovel and common sense are of as much use as the transit and tape in relocating an old corner.

will base his judgment on any other reliable evidence such as occupancy or the word of competent witnesses. It is obvious that this is along equitable lines, since the property was originally purchased with reference to the actual or visible bounds which vest the owner with rights to the property bounded by these lines.

If there is a dispute between adjoining owners over the location of a boundary line this presents a question which must be settled by the courts unless the parties can come to an agreement themselves. In such cases the surveyor acts simply as an expert in judging where the line originally ran and has no power to establish a new line. He can, however, be employed by the disputing parties as an arbitrator to decide on the equitable line, but they are not necessarily obliged to accept his judgment.

If they come to an agreement between themselves, however, regarding the location of the line and occupy to that line, this agreement is binding even though no court has intervened in the matter.

It is to be assumed that the deed was drawn by the grantor with honest intent to convey the property to the grantee. It is intended then that it shall be interpreted if possible so as to make it effectual rather than void. The deed should also be construed in the light of what was known at the time when the title was transferred.

In the interpretation of a deed it is assumed that it was intended to convey property the boundaries of which will form a closed traverse. Therefore it is within the jurisdiction of the surveyor to reject any **evident** mistake in the description when running out the property line, e.g., a bearing may have been recorded in the opposite direction or an entire side omitted. Where artificial features are mentioned as boundaries, these always take precedence over the recorded measurements or angles, but these marks must be mentioned in the deed in order to have the force or authority of monuments. When the area does not agree with the boundaries as described in the deed the boundaries control. All distances unless otherwise specified are to be taken as straight lines; but distances given as so many feet along a wall or highway are supposed to follow these lines even if they are not

straight. When a deed refers to a plan the dimensions on this plan become a part of the description of the property.

Where property is bounded by a highway the abutters usually own to the center line, but where it is an accepted street each abutter yields his portion of the street for public use; if, however, the street is abandoned the land reverts to the original owners. If a street has been opened and used for a long period bounded by walls or fences, and there has been no protest regarding them, these lines hold as legal boundaries. In the case of a line between private owners acquiescence in the location of the boundary will, in general, make it the legal line. But if there is a mistake in its location and it has not been brought to the attention of the interested parties or the question of its position raised, then occupancy for many years does not make it a legal line.

Where property is bounded by a non-navigable stream it extends to the thread of the stream. If the property is described as running to the bank of a river it is interpreted to mean to the low water mark unless otherwise stated. Where original ownership ran to the shore line of a navigable river and the water has subsequently receded the proper subdivision is one that gives to each owner along the shore his proportional share of the channel of the river. These lines will therefore run, in general, perpendicular to the channel of the stream from the original intersection of division lines and shore lines.

A more complete statement of the principles mentioned above particularly with reference to the U. S. Public Land Surveys will be found in an address on "The Judicial Functions of Surveyors," by Chief-Justice Cooley of the Michigan Supreme Court, read before the Michigan Association of Engineers and Surveyors, and published in the proceedings of the society for 1882, pp. 112-122.

152. RERUNNING OLD SURVEYS FROM A DEED.—The visible marks which are mentioned in a deed are of primary importance in determining the extent of a piece of property; the lengths of the sides and the bearings (or angles), which should agree with the boundaries, are of secondary importance. It sometimes occurs, however, that all evidences of artificial bound-

aries of the property or of portions of it are missing, and the surveyor must then fall back on the dimensions given in the deed as the best information available (Art. 150, p. 115). Furthermore it is sometimes necessary to "run out" an old deed to determine which of two lines is the correct boundary, or in some cases to find how close the actual boundaries of a property agree with the original deed.

If the directions of the boundaries are defined in the deed by the magnetic bearings, as was formerly the usual custom, it is necessary first to find the declination of the needle at the date of the original survey as well as the present declination of the needle and to correct all the bearings accordingly (Art. 29, p. 20). The declination of the needle should appear on the original deed or plan; but unfortunately it seldom does, and the year the survey was made must then be obtained either from the deed, the old plan, or from witnesses, and the declination of the needle at that time computed. Observations at different places and times have been compiled by the U. S. Coast and Geodetic Survey, and these results may be found in convenient form for calculation in the annual Reports of the Superintendent, particularly the 1886 report.* From these observations the approximate change in declination may be obtained. In this way the magnetic bearings, corrected to date, can be determined as closely probably as the original bearings were taken. It is evident that the **change** in the declination of the needle between the date of the original survey and the present time is what is desired. If there exists therefore one well-defined line which is known to be one of the original boundary lines, a bearing taken on this line and compared with that given in the deed will determine directly the change in declination. There may be more than one well-defined line whose bearings can be obtained and a comparison of the results on these different lines will give an idea of the reliability of the original survey as well as a more accurate determination of the change in declination.

* In 1902 the U. S. Coast and Geodetic Survey issued a special publication entitled, "Magnetic Declination Tables and Isogonic Charts for 1902," in which is given a very complete list of declinations for various places in the United States.

Not infrequently in attempting to rerun old compass surveys it is found that the traverse as described in the deed does not "close," i.e., the last point does not coincide with the first. If this error of closure is small it may be due to the difference in length between the chain used for the original survey and the one being used. Before any attempt is made to run out the old survey this difference should be determined by measuring one or more of the well-defined lines of the property, if any can be found, and comparing the measurements obtained with the recorded distances.

Occasionally it is found that the traverse will not close by a large amount owing to a mistake in the original survey. Often in such cases the deeds of adjacent property will show what the mistake was, and in such cases it is allowable to make a correction if it will give a description that is consistent. For example, it occasionally happens that a bearing has been recorded in the reverse direction so that no area is enclosed by the boundaries. Sometimes an entire chain-length has been omitted in one of the lines and by supplying this the description is made consistent. Other inconsistencies are to be dealt with in the same general manner, or as suggested in the preceding article.

153. How to Look Up a Recorded Deed. — In all the states of the Union the transfer of real property must be recorded in the respective county Registry of Deeds or in the office of the city or town clerk. At the Registry of Deeds is kept an exact copy of the deed, which can be examined by any one. It is frequently necessary for the surveyor to make use of these copies when it is not convenient to obtain the deed from the owner of the property or when it is necessary to look up the deed of adjacent property or previous transfers of any of them.

In every Registry of Deeds an index of the deeds is kept, which is divided into two parts, the *grantor* index and the *grantee* index; the grantor being the party who sells the land and the grantee the one who buys it. These indexes are frequently divided by years and for this reason the surveyor should know not only the name of the party who bought or sold the property (both if convenient to get them), but also the approximate date of the transaction. With this information he can readily find

in the proper index the name of the party, opposite which will appear the date of the transaction and the number of the deed book and page on which the copy of the deed is recorded. He then finds the deed book, from which he can copy whatever data he desires from the deed; usually the description of the property is all that concerns the surveyor. In the deed book is usually a reference number in the margin or in the text of the deed which refers to the next preceding transfer of the same property or to any attachments, assignments, and the like which may have been made on it. This method of indexing and filing deeds is used in the New England States and in many of the other states; in fact the general principles are the same throughout the country although the details may differ to some extent.

THE UNITED STATES SYSTEM OF SURVEYING THE PUBLIC LANDS.

154. The System.—The United States System of Surveying the Public Lands, which was inaugurated in 1784, and modified since by various acts of Congress, requires that the public lands “shall be divided by north and south lines run according to the true meridian, and by others crossing them at right angles so as to form townships six miles square,” and that the corners of the townships thus surveyed “must be marked with progressive numbers from the beginning.” Also, that the townships shall be subdivided into thirty-six sections, each of which shall contain six hundred and forty acres, as nearly as may be, by a system of two sets of parallel lines, one governed by true meridians and the other by parallels of latitude, the latter intersecting the former at right angles, at intervals of a mile.

Since the meridians converge it is evident that the requirement that the lines shall conform to true meridians and that townships shall be six miles square, is mathematically impossible. In order to conform as nearly as practicable to the spirit of the law, and also to make its application both uniform and effective, an elaborate system of subdivision has been worked out. This system will be described in this chapter, first in its general and afterward in its more detailed features; this will

then be followed by a discussion of the ways in which the work of present-time county and other local surveyors is related to the Public Lands System.

The work of the Public Lands Surveys is and has been carried on under the direction of the Commissioner of the General Land Office. Usually the area comprised in each State or Territory has been denominated a District, and has been placed in direct charge of a Surveyor General. The functions that the Surveyor General exercises in his District may be likened to those of a division engineer on construction work; he examines the Deputy Surveyors, approves their contracts, and inspects their fieldwork. The maps, field notes and other records are kept at his office until all the subdivision work in his district is completed, when they are turned over to the State to which they pertain, and the office of the Surveyor General is then discontinued. (See Art. 167, p. 153.)

The actual surveying operations are performed by Deputy Surveyors, who run the lines in the manner specified in the Manual * or as directed in detail by the Surveyor General. This work is usually done under contract, at stipulated prices per mile for lines of various degrees of importance or difficulty. These prices have varied from time to time, with the demand for and supply of deputies, the relative degree of accuracy with which the work was required to be done, and with other conditions. Those at present prescribed by law† are shown in Table 3.

It will be observed from the schedule of prices given that higher rates are paid for *standard* lines, which constitute the general framework or control for the subdivision work, and that the *township* lines in turn are rated higher than the *section* lines. It is the obvious intention, and has been the general practice, to secure a somewhat higher degree of accuracy for these more important lines by awarding them to the more experienced and skilful deputies, while inexperienced or less skilful surveyors were employed on subdivision work. It follows from this that

* Manual of Surveying Instructions for the Survey of the Public Lands issued by the Commissioner of the General Land Office, Washington, D. C.

† Act of Congress approved, March 3, 1905.

in the relocation of lost corners more weight may properly be given to the more important lines.

TABLE 3.

SHOWING PRESCRIBED RATES OF PAYMENT PER LINEAR MILE FOR
SURVEYING PUBLIC LANDS.

	Standard and Meander Lines.	Township Lines.	Section Lines.
Minimum rates: to be used under ordinarily favorable conditions.	\$ 9	\$ 7	\$ 5
Intermediate rates: to be applicable to lands "heavily timbered, mountainous, or covered with dense undergrowth, but not exceptionally difficult to survey."	\$13	\$11	\$ 7
Maximum rates: to be allowed only in cases of exceptional difficulties in the surveys.	\$18	\$15	\$12
Special maximum rates: to be allowed in cases of exceptional difficulties in the surveys, in certain remote districts, at the discretion of the Secretary of the Interior.	\$25	\$23	\$20

In the following named States and Territories the surveying of Public Lands is still in progress, the work being under the supervision of Surveyors General.*

154a. Process of Subdivision. — It will be convenient to consider the process of subdivision as separated into several distinct operations, to be carried out in sequence. It must be understood, however, that one operation, for instance, the division of the area into 24-mile tracts, is rarely or never completed over the entire

* From Report of the Commissioner of the General Land Office for the Year ended June 30, 1906.

† Practically completed.

the meridian through that point. The field methods prescribed for running out the principal meridian and the base-line on the ground are described in detail in Arts. 155a-b, pp. 129-31.

SECOND. The division of the area to be surveyed into tracts approximately 24 miles square (Fig. 57) by the establishment of

(a) *Standard Parallels* conforming to true parallels of latitude through the 24-mile points previously established on the principal meridian, and extending both east and west therefrom, and

(b) *Guide Meridians* conforming to true meridians of longitude through the 24-mile points previously established on the base-line and standard parallels, and extending north therefrom to an intersection with the next standard parallel or to the base-line.

Since the guide meridians converge, these 24-mile tracts will be 24 miles wide on their southern and somewhat less than this on their northern boundaries. Theoretically, both the east and the west boundaries should be just 24 miles in length, but, owing to discrepancies of field measurements, this is rarely or never the case.

THIRD. The division of each 24-mile tract into *Townships*, each approximately 6 miles square, by the establishment of

(a) Meridional lines, usually called *Range Lines*, conforming to true meridians through the standard township corners previously established at intervals of 6 miles on the base-line and standard parallels, and extending north therefrom to an intersection with the next standard parallel, or to the base-line, and

(b) Latitudinal lines, sometimes called *Township Lines*, joining the township corners previously established at intervals of 6 miles on the principal meridian, guide meridians, and range lines. The division resulting from the first three operations is indicated in Fig. 57a.

It will be apparent that, neglecting the effect of discrepancies and irregularities in measurement, both the east and the west boundaries of all townships will be just 6 miles in length, but the north and south boundaries will vary in length from a maximum at the standard parallel or base-line forming the southern limit of the 24-mile tract to a minimum at that forming its northern limit.

154b. Methods of Designating Lines and Areas.— The various principal meridians and base-lines of the Public Lands Surveys are designated by definite names or by number, as, for example, "The Fifth Principal Meridian and Base-Line," or "The Cimarron Meridian."

The standard parallels are numbered in order both north and south from the base-line, and are so designated. The guide meridians are numbered in a similar manner east and west from the principal meridian. Fig. 57 illustrates the method.

Any series of contiguous townships or sections situated north and south of each other constitutes a *range*, while such a series situated in an east and west direction constitutes a *tier*.

The tiers of townships are numbered in order, to both the north and the south, beginning with number 1 at the base-line; and the ranges of townships are numbered to both the east and the west, beginning with number 1 at the principal meridian. A township is designated, therefore, by its serial number north or south of the base-line followed by its number east or west of the principal meridian, as "Township 7 south, Range 19 east, of the Sixth Principal Meridian." This is usually shortened to "T. 7 S., R. 19 E., 6th P. M."

The sections of a township are numbered commencing with No. 1 at the northeast angle of the township, and proceeding west to No. 6, and then proceeding east to No. 12, and so on, alternately, to No. 36, in the southeast angle as illustrated by Fig. 57b. In all cases of surveys of fractional townships the sections will bear the same numbers they would have if the township were complete.

The regular subdivisions of a Section are indicated by stating

6	5	4	3	2	1
7	8	9	10	11	12
18	17	16	15	14	13
19	20	21	22	23	24
30	29	28	27	26	25
31	32	33	34	35	36

FIG. 57b. DIAGRAM OF A TOWNSHIP ILLUSTRATING METHOD OF NUMBERING THE SECTIONS.

briefly the aliquot part of the section intended together with its location in the section, as "the N. $\frac{1}{2}$ of the S.W. $\frac{1}{4}$ of Sec. 27, T. 12 N., R. 5 W."

154c. Field Methods. — The work of subdivision of the Public Lands has already been largely completed, and the surveyor of to-day is usually concerned only with the retracing of old lines, the relocation of lost corners, or with the subdivision work that comes with increase in population. For all these, however, a thoroughgoing knowledge of at least the common field processes and methods that have been used in the original surveys is essential. Certain details of field practice have varied somewhat from time to time, but the leading features have remained fairly constant for all those areas that have been surveyed since the system became well established.

In the following pages is given a somewhat detailed description of the methods commonly employed in carrying out the operations briefly indicated in Art. 154a. Inasmuch, however, as certain of the east and west lines are required to be established as true parallels of latitude, the two commonly accepted methods of accomplishing this will first be described.

155. TO ESTABLISH A PARALLEL OF LATITUDE. — A parallel of latitude on the surface of a sphere is a curved line. This may be understood from the facts that the meridians converge toward the pole, and that a parallel is at every point at right angles to the meridian at that point. If vertical lines are drawn through every point on a parallel of latitude they will form a conical surface, the apex of the cone being at the center of the sphere. In the case of a straight line all of the verticals would lie in the same plane, and this plane would intersect the sphere in a great circle.

A parallel of latitude may be run out by means of the solar attachment to the transit, since by using this instrument the direction of the meridian may be quickly found whenever the sun is visible (Art. 85, p. 66). A line which at every point is at right angles to the meridian will be a true parallel of latitude. This method, however, is found to give results less accurate than are required, chiefly on account of the errors in the adjustment of the solar attachment.

A better method of establishing a parallel is by taking offsets from a straight line. Two methods of doing this, known as the *Secant Method* and the *Tangent Method*, are used in the Public Lands Surveys.

155a. The Secant Method.* — (Fig. 58.) "This method consists of running a connected series of straight lines, each six miles long, on such courses that any one of the lines will intersect the curve of the parallel of latitude in two points, separated by an interval of four miles; and from this line thus established, measuring north or south, as the case may be, to attain other required

FIG. 58. SECANT METHOD FOR ESTABLISHING A PARALLEL OF LATITUDE.

points on the latitude curve." The 0 and 6 mile points of a parallel will be north of the secant, and the 2, 3, and 4 mile points will be south of the secant.

The instrument is set up south of the township corner where the survey is to begin, the distance from the corner being found in Table 4 in the column headed "0 miles." For example, in latitude 40° the transit would be set 2.79 feet south of the corner. The direction of the first secant at its initial point is found by observing on Polaris (Chapter VII) to obtain the true meridian and then laying off the azimuth angle found in Table 4 under "0 miles." (See Fig. 58.) This angle should be repeated several times to determine accurately the direction of the secant. This direction is then prolonged 6 miles. At each mile and half-mile point an offset is measured to establish a point on the curve, the distance and direction of the offset being shown in Table 4.

* The quotations are from the "Manual of Surveying Instructions for the Survey of the Public Lands of the United States," prepared by the Commissioner of the General Land Office in 1902.

Azimuths and offsets at —								

When the 6-mile point is reached the direction of a new secant is found by turning off to the north the deflection angle given in the right-hand column of Table 4. The offsets are then measured from this line as from the preceding one. The chief advantage of this method is that the offsets are short and hence much cutting is saved in wooded regions.

"With ordinary field instruments, usually reading to single minutes only, fractional parts of the 'least count' are generally estimated by the eye. Greater accuracy may be attained by making use of a linear measure to lay off deflection angles." In the right-hand column of Table 4 are given linear dimensions

FIG. 58a. TANGENT METHOD FOR ESTABLISHING A PARALLEL OF LATITUDE.

suitable for use in laying off the deflection angles corresponding to the various latitudes noted. In using this extremely valuable method of laying off small angles, a point is first carefully marked, by double centering, at a distance of one chain (66 feet) from the instrument. A scale divided to decimals of an inch is then used to measure off toward the north the appropriate distance taken from the Table, and the vertical cross-wire of the transit is moved through the angle subtended. The reading of the vernier will check the measurement and guard against large errors. The direction thus determined is then prolonged in the usual manner.

155b. "The Tangent Method.—This method consists in laying off from a true meridian, established by observations on Polaris at elongation, an angle of 90° , producing the direction thus determined, a distance of 6 miles, in a straight line, and

measuring north therefrom, at half-mile intervals, distances of correct length, taken from Table 6 (interpolated if necessary), for the given latitude, to attain other points on the latitude curve passing through the tangential or initial points.

"The azimuth or bearing of the tangent at successive mile points will be taken from Table 5 to the nearest whole minute only, and will be inserted in the field notes, no interpolation being required, except when test sights are taken. The true bearing between two points on a standard parallel will be derived from Table 5 by taking it in the column headed with one-half the distance between said points. The offsets at intervals of one mile are inserted in Table 6; to obtain the length of offsets at the half-mile points, take one-fourth of the offset corresponding to twice the distance of the half-mile point from the tangential point.

"This method is suitable for running standard parallels and latitudinal township lines in a level open country, where no intersections with topographical features will be required; but in all cases the secant method will be found most convenient."

156. Initial Points. — Initial points from which the lines of the public surveys are to be extended will be established whenever necessary, under such special instructions as may be prescribed in each case by the Commissioner of the General Land Office. The locus of such initial points will be selected with great care and due consideration for their prominence and easy identification, and must be established astronomically.

"An initial point should have a conspicuous location, visible from distant points on lines; it should be perpetuated by an indestructible monument, preferably a copper bolt firmly set in a rock edge; and it should be witnessed by rock bearings, without relying on anything perishable like wood."

157. Base-Line. — From the initial point the base-line is extended both east and west on a true parallel of latitude, one of the methods described in the foregoing paragraphs being used. Great care is taken to secure instrumental accuracy. Two back and two fore sights are taken at each setting of the instrument, the horizontal limb being revolved 180° in azimuth between the observations, in one method, taking the mean of observations. Another method, called double back and fore

sights, is still more exact, and therefore preferable. In this process the vertical cross-wire is fixed upon two transit points at some distance apart, in the rear, and then reversed to set one or two new points in advance. This not only insures a straight line, if the transit is leveled, but also detects the least error of collimation. (See Art. 64, p. 52.)

"Where solar apparatus is used in connection with a transit, the deputy will test the instrument, whenever practicable, by comparing its indications with a meridian determined by Polaris observations; and in all cases where error is discovered he will make the necessary corrections of his line before proceeding with the survey. All operations will be fully described in the field notes.

"In order to detect errors and insure accuracy in measurement, two sets of chainmen will be employed; one to note distances to intermediate points and to locate topographical features, the other to act as a check. Each will measure 40 chains, and in case the difference is inconsiderable, the proper corner will be placed midway between the ending points of the two measurements; but if the discrepancy exceed 8 links on even ground, or 25 links on mountainous surface, the true distance will be found by careful re-chaining by one party or both.

"The deputy will be present when each corner is thus established, and will record in the body of his field notes the distances to the same, according to the measurement by each set of chainmen.

"To obviate collusion between the sets of chainmen, the second set should commence at a point in advance of the beginning corner of the first set, the initial difference in measurement thus obtained being known only to the deputy."

The proper township, section, and quarter-section corners are established at the appropriate intervals, and meander and witness corners (Arts. 165a-c, pp.148-9.) are set wherever the line crosses such streams, lakes, bayous, or other objects as may make their use necessary. Stones or posts used to mark the positions of the township or section corners are marked on their north face with the letters SC, for "standard corner," for

the purpose of easily distinguishing them from the "closing corners," to be set later.

158. Principal Meridian. — The principal meridian is extended as a true meridian of longitude both north and south from the initial point. The methods used for the determination of directions, and the precautions observed to secure accuracy of measurement, are the same as those described in the preceding article, under the subject of "Base-Line."

Also, as in the case of the base-line, all township, section, quarter-section, and other necessary corners are established in the proper places as the survey proceeds.

159. Standard Parallels. — Standard parallels, which are also sometimes referred to as *correction lines*, are extended both east and west from every fourth township corner previously established on the principal meridian. Sometimes, however, the distance between them is more or less than 24 miles, depending upon the requirements of the particular survey in question. For example, in Kansas the correction lines occur at regular intervals of 30 instead of 24 miles. In all cases deviations from the regular order are made only under the written special instructions of the Surveyor General. The Manual provides further that "where gross irregularities (in previous surveys) require additional standard lines, from which to initiate new, or upon which to close old surveys, an intermediate correction line should be established to which a local name may be given, e.g., 'Cedar Creek Correction Line'; and the same will be run, in all respects, like the regular standard parallels."

Standard parallels are established as true parallels of latitude, and are run in the same manner and with the same precautions for accuracy as in the survey of the base-line.

Appropriate corners are established at the proper intervals, and the township and section corners are marked *SC* on their north face, the same as those on the base-line.

160. Guide Meridians. — Guide meridians are extended north from the base-line, or standard parallels, at intervals of 24 miles east and west from the principal meridian. They are run as true meridians of longitude, and are extended to an intersection with the next correction line north. At the point of intersection

of the guide meridian with the correction line a *closing corner* is established, and the stone or post is marked on its **south** face with the letters *CC*, to distinguish it from the standard corners already in place. Also, the distance of the closing corner from the nearest standard corner is measured and recorded in the field notes. This correction offset will vary with the latitude and with the distance of the corner from the principal meridian. At a distance of 15 or 20 ranges from the principal meridian it may be so great that the closing corner will be nearer to the adjacent quarter-section corner than to the standard township corner. Furthermore, it is obvious that the closing corners will be west of the corresponding standard corners on the east side of the principal meridian, and east of them on the west side.

The mile and half-mile distances on the guide meridians are made full 80 and 40 chains in length until the last half-mile is reached, into which all excess or deficiency due to discrepancies of measurement is thrown.

The general method of running the guide meridians is the same as that used in running the principal meridian, and all the provisions for securing accuracy of alignment and measurement, and for establishing corners, prescribed for the latter apply to the former also.

Provision is made for running guide meridians from north to south where existing local conditions require this departure from the usual practice. In such a case the closing corner is first established on the correction line by calculating the proper correction distance and laying it off from the standard corner; and then the guide meridian is run due south from this point. This method may be used in case the standard corner from which the guide meridian would ordinarily originate is inaccessible, or for other adequate reasons.

The Manual also provides that "where guide meridians have been improperly placed at intervals greatly exceeding the authorized distance of 24 miles, and standard lines are required to limit errors of old, or govern new surveys, a new guide meridian may be run from a standard, or properly established closing corner, and a local name may be assigned to the same, e.g., 'Grass Valley

Guide Meridian.' These additional guide meridians will be surveyed in all respects like regular guide meridians."

161. Township Exteriors. — The usual method of subdividing a 24-mile tract into townships is as follows (see Fig. 57a).

Beginning at the standard corner at the southeast corner of the southwest township in the tract, the surveyor runs north on a true meridian of longitude a distance of 6 miles, setting all necessary corners by the way. From the township corner thus established he runs due west on a random line (Art. 191, p. 169) to intersect the guide meridian (or the principal meridian, in case he is working in Range 1 East), setting temporary section and quarter-section corners as he goes. When he intersects the meridian, he notes the "falling" * of his random line, and, in case this is within the limit prescribed, he then calculates the course of the true line joining the two township corners and runs back on it, setting permanent corners opposite the temporary ones previously set on the random line. In this way all the deficiency due to the convergence of the meridional boundaries of the township, together with whatever excess or deficiency may arise from inaccuracies in measurement, are thrown into the most westerly half-mile of the latitudinal boundary.

The range line is now continued as a true meridian for another 6 miles, permanent corners being set as before. Then another random line is thrown across to the western boundary of the range of townships, and is corrected back to the true line, in the same manner as that just described. This process is continued until the most northerly township in the 24-mile tract is reached, when the range line is merely continued as a true meridian to an intersection with the correction line, at which point a closing township corner is established. The half-mile intervals on the range line are made full 40 chains for the entire 24 miles; except the most northerly half-mile, into which all excess or deficiency due to irregularities of measurement is thrown.

The two other range lines of the 24-mile block are run in a similar manner, the latitudinal township lines being extended to

* That is, the distance of the point at which the random line intersects the meridian from the objective corner.

the westward at the proper intervals and made to connect with the township corners previously established. From the township corners on the last range line, however, random lines are run also to the eastward to meet the guide meridian, and are then corrected back to the westward on a true line between the township corners. This is done in such a way that the excess or deficiency of this line also is thrown into the most westerly half-mile.

"In cases where impassable obstacles occur and the foregoing rules cannot be complied with, township corners will be established as follows:

"In extending the south or north boundaries of a township to the west, where the southwest or northwest corners cannot be established in the regular way by running a north and south line, such boundaries will be run west on a true line, allowing for convergency on the west half-mile; and from the township corner established at the end of such boundary, the west boundary will be run north or south, as the case may be. In extending south or north boundaries of a township to the east, where the southeast or northeast corner cannot be established in the regular way, the same rule will be observed, except that such boundaries will be run east on a true line, and the east boundary run north or south, as the case may be. Allowance for the convergency of meridians will be made whenever necessary."

The Manual provides for a maximum allowable limit for closing the random line upon the township corner, as follows: "If in running a random township exterior, such random exceeds or falls short of its proper length by more than 3 chains, allowing for convergency, or falls more than 3 chains to the right or left of the objective point (or shows a proportionate error for lines of greater or less length than 6 miles), it will be re-run, and if found correctly run, so much of the remaining boundaries of the township will be retraced, or resurveyed, as may be found necessary to locate the cause of misclosure." A lateral displacement of 3 chains in a distance of 6 miles is equivalent to an angular deviation of 21 minutes.

162. Subdivision of Townships.— In the subdivision of a township into sections the following routing is followed in the field. The surveyor sets up his instrument at the southeast

corner of the township, observes the meridian, and retraces the range line northward for a distance of one mile, and the township line westward for the same distance. This is for the purpose of comparing his own meridian and needle observations and the length of his chain with those of the previous surveyor who laid off the township exteriors.* Then from the southwest corner of Section 36 he runs north on a line parallel with the east boundary of the township, setting a quarter-section corner at 40 chains and a section corner at 80 chains. Then from the section corner just set he runs east on a random line, parallel to the south boundary of the section, setting a temporary quarter-section corner at 40 chains. When he intersects the range line he notes the falling of his random and also the distance it overruns or falls short of the length of the south boundary of the section. If the falling is not more than 50 links (33 feet, representing an angular deviation of 21 minutes), and if the distance overruns or falls short of the length of the southern boundary of Section 36 by not more than the same amount, a return course which will join the two section corners is calculated; this new line is then run toward the west, the permanent quarter-section corner being set at its middle point.

From the section corner just regained the survey is now continued north between Sections 25 and 26, the direction being changed slightly to the east or west according to whether the latitudinal section line just completed exceeded or fell short of the desired length. At 40 and 80 chains on this line the quarter-section and section corners, respectively, are set, and from the section corner a random is run across to the range line, and a return course is calculated and run as before. This process is continued until five of the six sections in the series are inclosed. Then, if the north boundary of the township is not a correction line, from the section corner last established a random is run north to the township boundary, and from the data thus secured a true line is calculated and run from the section corner on the township line back to the initial corner. If the north boundary of the township is a correction line, however, the point at which

* See specimen field notes, p. 144.

the random intersects this boundary is established as a **closing corner** and its distance from the nearest **standard corner** is measured and recorded. In either case the permanent quarter-section corner is established at 40 chains north of the initial corner, the excess or deficiency being thrown into the most northerly half-mile.

In a similar manner the succeeding ranges of sections are enclosed, randoms being run across eastward to the section corners previously established and true lines corrected back. From the fifth series of section corners thus established, however, random lines are projected to the westward also, and are closed on the corresponding section corners in the range line forming the western boundary of the township. In correcting these lines back, however, the permanent quarter-section corners are established at points 40 chains from the initial corners of the randoms, thereby throwing all fractional measurements into the most westerly half-miles. Reference to Figs. 59 and 60 will help toward an understanding of this method of subdivision.

Table 6a, taken from the Manual, gives (to the nearest whole minute) the angular convergency of meridians from one to five miles apart. The meridional section lines, therefore, by reason of being (theoretically) parallel to the range line on the east boundary of the township, will depart from true meridians by the amounts indicated in the table.

TABLE 6a.

CORRECTIONS FOR CONVERGENCY WITHIN A TOWNSHIP.

Latitude.	Correction to be applied to bearing of range lines at a distance of —				
	1 mile.	2 miles.	3 miles.	4 miles.	5 miles.
0° 0'	1	1	2	2	3
30 to 35	1	1	2	3	3
35 to 40	1	2	2	3	4
40 to 45	1	2	3	4	5
45 to 50	1	2	3	5	6
50 to 55	1	3	4	5	7
55 to 60	2	3	5	7	8
60 to 65	2	4	6	8	10
65 to 70					

From a consideration of the foregoing it will be apparent

(1) That interior meridional section lines are 80 chains in length, except those next to the north boundary of the township; and that the south half of these is 40 chains.

(2) That interior latitudinal section lines are within 50 links of the length of the line forming the southern boundary of the range of sections, except those section lines next to the west boundary of the township; and that the east half of these is 40 chains.

(3) That interior section lines, whether meridional or latitudinal, are ordinarily straight for one mile only.

(4) That except in those section lines next to the north and west boundaries of the township, the quarter-section corners are placed equidistant from the two section corners on either side.

(5) That meridional section lines are intended to be parallel to the range line forming the eastern boundary of the township; and similarly, that latitudinal section lines are intended to be parallel to the township line forming its southern boundary.

(6) That the cumulative deficiency in latitudinal lines due to the convergence of the meridians is thrown into the most westerly half-mile of the township.

(7) That no quarter-section closing corners are established on correction lines for the use of the sections south of these lines.

163. Fractional Sections. — In sections made fractional by rivers, lakes, or other bodies of water, lots are formed bordering on the body of water, and numbered consecutively through the section. The boundaries of these lots usually follow the quarter lines of the section, and contain, as nearly as may be, forty acres each. Fig. 59 indicates the method. Also, the quarter quarter sections along the north and west boundaries of a township, into which the discrepancies of measurements or the deficiencies due to the convergence of the range lines are to be carried when the sections are subdivided, are usually numbered and sold as lots. (See Art. 169, p. 153d.) These lot lines are not actually run in the field, but, like the quarter-section lines, are merely indicated on the plates, and the areas by which the lots are sold are computed in the office.

Field notes taken in connection with the survey of public lands are required to be returned to the General Land Office in the narrative form. A sample page of notes, somewhat condensed from those given in the Manual, is herewith presented

FIG. 59. SHOWING PART OF A TYPICAL TOWNSHIP; ALSO SHOWING METHOD OF FORMING LOTS IN FRACTIONAL SECTIONS.

for its value not only as an illustration of a section line survey but also as an instructive example of this very valuable method of note keeping. Fig. 59, also from the Manual, shows the nine sections in the southeastern part of a typical township, and illustrates the specimen notes given.

SPECIMEN OF FIELD NOTES.

SUBDIVISION OF T. 15 N., R. 20 E.

Chains.	From the Tp. cor. already described,* I run North, on the 5th Guide Meridian and E. bdy. of sec. 36; and, at 40.01 chs., intersect the $\frac{1}{4}$ sec. cor.; and, at 79.98 chs., fall 1 lk. W. of the cor. of secs. 25, 30, 31, and 36; therefore, the line bears north. From the Tp. cor. I run N. $89^{\circ} 57'$ W., on the S. bdy. of sec. 36; at 39.99 chs., fall $0\frac{1}{4}$ lk. N. of the $\frac{1}{4}$ sec. cor.; and at 80.01 chs. fall 1 lk. S. of the cor. of secs. 1, 2, 35, and 36, on S. bdy. of the Tp.; consequently, the S. bdy. of the sec. 36 bears N. $89^{\circ} 57'$ W. Therefore, the bearings are as stated by the surveyor general, and my chaining practically agrees with the field notes of the original survey. I commence at the cor. of secs. 1, 2, 35, and 36, on the S. bdy. of the Tp., which is a sandstone, $6 \times 8 \times 5$ ins. above ground, firmly set, and marked and witnessed as described by the surveyor general. Thence I run N. $0^{\circ} 01'$ W., bet. secs. 35 and 36. Over level bottom land.
4.50	Wire fence, bears E. and W.
20.00	Enter scattering cottonwood timber, bears E. and W. F. G. Alexander's house bears N. 28° W.
29.30	Leave scattering cottonwoods, bearing E. and W.; enter road, bears N.
30.00	SE. cor. of F. G. Alexander's field; thence along west side of road.
39.50	To crossroads, bears E. to Mound City; N. to Lake City. F. G. Alexander's house bears S. 40° W. The $\frac{1}{4}$ sec. cor. point will fall in road; therefore
	Set a cedar post, 3 ft. long, 3 ins. sq., with quart of charcoal, 24 ins. in the ground, for witness cor. to $\frac{1}{4}$ sec. cor., marked W C $\frac{1}{4}$ S 35 on W. and 36 on E. face; dig pits, $18 \times 18 \times 12$ ins. N. and S. of post, 3 ft. dist.; and raise a mound of earth $3\frac{1}{2}$ ft. base, $1\frac{1}{2}$ ft. high. W. of cor.
40.00	Point for $\frac{1}{4}$ sec. cor. in road. Deposit a marked stone, 24 ins. in the ground, for $\frac{1}{4}$ sec. cor. The SE. cor. of Pat. Curran's field bears W., 5 lks. dist.
40.50	Set a limestone, $15 \times 8 \times 6$ ins. 10 ins. in the ground, for witness cor. to $\frac{1}{4}$ sec. cor., marked W C $\frac{1}{4}$ S on W. face; dig pits, $18 \times 18 \times 12$ ins. N. and S. of stone, 3 ft. dist.; and raise a mound of earth, $3\frac{1}{2}$ ft. base, $1\frac{1}{2}$ ft. high, W. of cor. Thence along E. side of field.
50.50	NE. cor. of Pat. Curran's field, bears W. 4 lks. dist.
51.50	Leave road; which turns to N. 70° W., leads to ferry on Yellowstone River; thence to Lake City.
57.50	Enter dense cottonwood and willow undergrowth, bears N. 54° E. and S. 54° W.
72.50	Leave undergrowth, enter scattering timber, bears N. 60° E. and S. 60° W.
80.00	Set a locust post, 3 ft. long, 4 ins. sq., 24 ins. in the ground, for cor. of secs. 25, 26, 35 and 36, marked T 15 N S 25 on NE., R 20 E S 36 on SE., S 35 on SW., and S 26 on NW. face; with 1 notch on S. and E. faces; from which An ash, 13 ins. diam., bears N. 22° E., 26 lks. dist., marked T 15 N R 20 E S 25 B T. A sycamore, 23 ins. diam., bears S. $71\frac{1}{2}^{\circ}$ E., 37 lks. dist., marked T 15 N R 20 E S 36 B T. A walnut, 17 ins. diam., bears S. 64° W., 41 lks. dist., marked T 15 N R 20 E S 35 B T. A cottonwood, 13 ins. diam., bears N. $21\frac{1}{2}^{\circ}$ W., 36 lks. dist., marked T 15 N R 20 E S 26 B T.

* Description omitted. A description of the determination of a true meridian by both solar and Polaris observations is also omitted.

164. "Summary of objects and data intersected by the line or in its vicinity, to be noted. — 1. The precise course and length of every line run, noting all necessary offsets therefrom, with the reason for making them, and method employed.

"2. The kind and diameter of all bearing trees, with the course and distance of the same from their respective corners; and the precise relative position of witness corners to the true corners.

"3. The kind of materials of which corners are constructed.

"4. Trees on line. The name, diameter, and distance on line to all trees which it intersects.

"5. Intersections by line of land objects. The distance at which the line intersects the boundary lines of every reservation, town site, donation claim, Indian allotment, settler's claim, improvement, or rancho; prairie, bottom land, swamp, marsh, grove, and windfall, with the course of the same at all points of intersection; also, the distances at which the line begins to ascend, arrives at the top, begins to descend, and reaches the foot of all remarkable hills and ridges, with their courses, and estimated height in feet, above the level land of the surrounding country, or above the bottom lands, ravines, or waters near which they are situated. Also, distance to and across large ravines, their depth and course.

"6. Intersections by line of water objects. All rivers, creeks, and smaller streams of water which the line crosses; the distances measured on the true line to the bank first arrived at, the course down stream at points of intersection, and their widths on line. In cases of navigable streams, their width will be ascertained between the meander corners, as set forth under the proper head.

"7. The land's surface — whether level, rolling, broken, hilly, or mountainous.

"8. The soil — whether rocky, stony, sandy, clay, etc., and also whether first, second, third, or fourth rate.

"9. Timber — the several kinds of timber and undergrowth, in the order in which they predominate.

"10. Bottom lands — to be described as wet or dry, and if subject to inundation, state to what depth.

"11. Springs of water — whether fresh, saline, or mineral, with the course of the streams flowing from them.

"12. Lakes and ponds — describing their banks and giving their height, and whether it be pure or stagnant, deep or shallow.

"13. Improvements. Towns and villages; houses or cabins, fields, or other improvements with owners' names; mill sites, forges, and factories, U. S. mineral monuments, and all corners not belonging to the system of rectangular surveying; will be located by bearing and distance, or by intersecting bearings from given points.

"14. Coal banks or beds; peat or turf grounds; minerals and ores; with particular description of the same as to quality and extent, and all diggings therefor; also salt springs and licks. All reliable information that can be obtained respecting these objects, whether they be on the line or not, will appear in the general description.

"15. Roads and trails, with their directions, whence and whither.

"16. Rapids, cataracts, cascades, or falls of water, with the estimated height of their fall in feet.

"17. Precipices, caves, sink holes, ravines, remarkable crags, stone quarries, ledges of rocks, with the kind of stone they afford.

"18. Natural curiosities, interesting fossils, petrifications, organic remains, etc.; also all ancient works of art, such as mounds, fortifications, embankments, ditches or objects of like nature.

"19. The magnetic declination will be incidentally noted at all points of the lines being surveyed, where any material change in the same indicates the probable presence of iron ores; and the position of such points will be perfectly identified in the field notes."

165. MARKING CORNERS. — Corners are marked on the ground by various kinds of monuments, depending upon the character and importance of the corner to be perpetuated, the soil, the materials available, and upon other local and special conditions. In places where stone is plentiful monuments of this material are usually set. In timbered districts where suitable stones are difficult to obtain, posts are driven to mark the points. In prairie regions where neither stones nor timber are available

a mound of earth may be raised over the corner, a small marked stone, a charred stake, a quart of charcoal, or some other permanent and distinguishable mark being deposited beneath it. Occasionally in the timber the corner falls on a spot occupied by a tree, in which case the tree itself may stand as the monument.

FIG. 60. SHOWING THE SUBDIVISION OF A TOWNSHIP INTO SECTIONS AND THE METHOD COMMONLY USED FOR MARKING TOWNSHIP AND SECTION CORNERS.

In case stones or posts are set they are marked with notches as shown in Figs. 60 and 60a, in order to indicate their respective positions in the township. Section corners on range lines, including under this term principal and guide meridians, are marked with notches on their north and south faces, the number

of notches being equal to the number of miles to the next adjacent township corner north or south. In a similar manner the section corners on the township lines, including base-lines and standard parallels, are notched on their east and west faces. Township corners, being located on both range and township lines, are marked with six notches on each of the four sides. In addition to being notched as just indicated, corners on correction lines are marked *SC* on their northern or *CC* on their southern faces,

FIG. 60a. SKETCH OF STONE MONUMENT, SHOWING NOTCHES.

depending upon whether they are standard or closing corners. Section corners in the interior of a township are given notches on their east and south faces corresponding to the number of miles to the east and south boundaries of the township. Thus, the corner common to sections 20, 21, 28, and 29 would have two

notches on the south and four on the east face, as sketched in Fig. 60a. Quarter-section corners are marked with the fraction " $\frac{1}{4}$ ", those on meridional lines on their west and those on latitudinal lines on their north faces.

165a. Witnessing Corners. — Wherever possible the monument set at a corner is witnessed by several nearby objects, which may be easily found by anyone looking for the corner itself, which are not readily moved or obliterated, and which are comparatively permanent. In timbered country the stone or post is usually witnessed by "bearing trees" located near the corner. The process of establishing a witness tree is to take its bearing and distance from the corner, then to blaze off the bark from a short section of the trunk on the side facing the corner and to cut into the wood with scribing tools certain letters and numerals indicative of the section in which the tree is located. For example, the tree northeast from the corner shown in Fig. 60a might be marked

T	7	S
R	15	E
S	21	
B	T,	

the letters and figures being abbreviations of "Township 7 south, Range 15 east, Section 21, Bearing Tree." Usually one tree is marked in each of the sections to which the corner refers, provided suitable trees can be found within a reasonable distance of the corner.

In prairie regions small rectangular pits are dug near to the corner, the earth taken from them being used to form a mound. These pits are placed either on the section lines leading from the corner or at angles of 45 degrees with these lines, depending on the kind of corner witnessed; and the mound may be either alongside the monument or, in case the monument is merely a deposit beneath the surface of the ground, may be placed immediately over it. Fig. 6ob, adapted from illustrations given in the Manual, indicates the manner of using this method of witnessing corners of the several classes. Marks of this kind are of much greater value than might at first be supposed, for, although the sharp outlines are quickly worn away, the grass sod soon covers the mound and grows down into the pits and preserves them from entire obliteration. In many places on the plains four slight depressions in the prairie sod with a little mound between have perpetuated the location of the section corner for a generation or more, until the country has been settled up and the fence lines strung. Under other prevailing conditions corners have been witnessed by mounds of stone, by prominent boulders, and by various other suitable objects.

165b. Witness Corners. — In case a regular corner falls in a creek, pond, or in any other place where it is impracticable to set or maintain a monument, *witness corners* are set on all the lines leading to this corner. These are marked with the letters *WC* in addition to the markings that would be appropriate to the corner of which they are witnesses. Witness corners are, in turn, referenced by bearing trees, pits and mounds, and other objects, the same as true corners.

165c. Meander Corners. — Where a surveyed line intersects the bank of a stream whose width is more than three chains, or of a lake, bayou or other body of water having considerable extent, a *meander corner* is established. The distance from the nearest section or quarter-section corner is measured and recorded

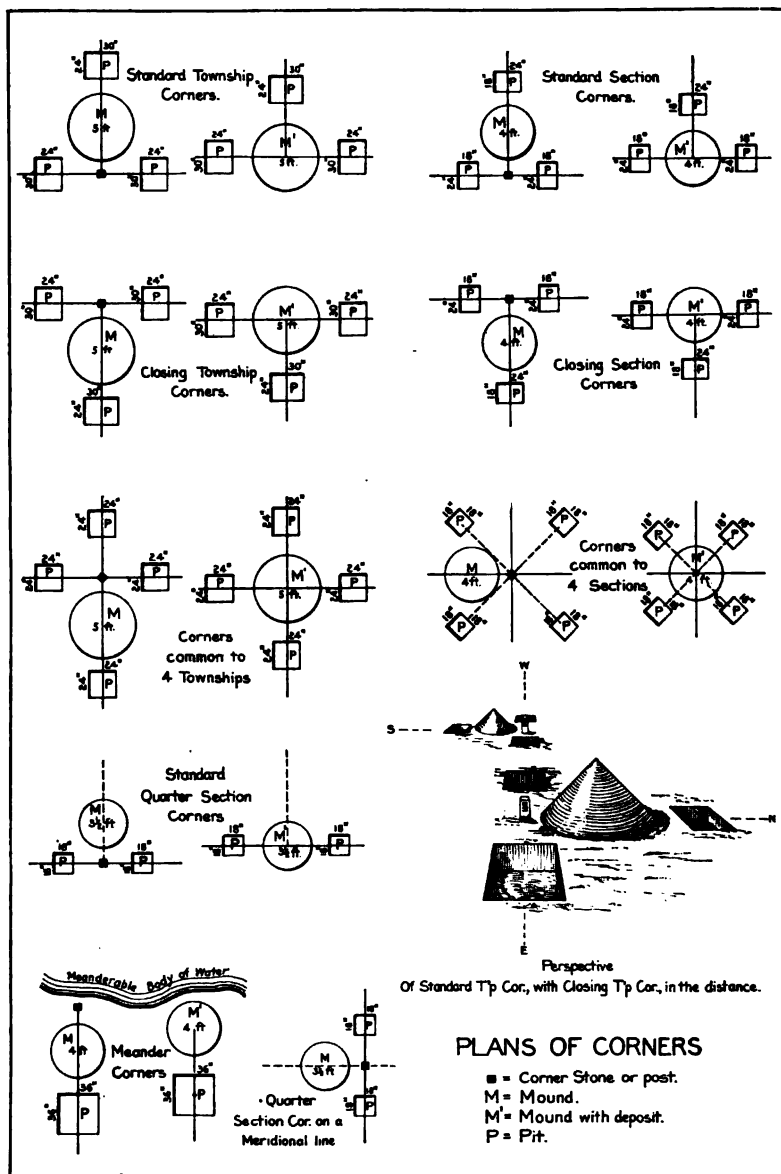

FIG. 60b. SHOWING SCHEME FOR DESIGNATING CORNERS BY MEANS OF MOUNDS AND PITS.

in the notes, and the stone or post set as a monument is marked *MC* on the side facing the water, and the point is referenced by bearing trees or by mounds of earth in much the same manner as a quarter-section corner. If practicable, the line is then carried across the stream or other body of water by triangulation to another meander corner set in line on the further bank, and the survey is continued.

166. MEANDERING.— After the regular subdivision work has been done traverses are run, usually by the needle, joining the successive meander corners along the banks of the streams or lake. A traverse of this kind, or a *meander line*, as it is called, originates at a meander corner and follows as closely as may be practicable the various sinuosities of the bank until the next meander corner is reached. Here the traverse is checked by calculating the position of the new meander corner and comparing this with its known position on the surveyed line, and the meandering is then continued. Fig. 61 illustrates the relation of meander corners and lines to the regular lines of the survey. These meander lines are used in plotting the stream on the map and in calculating the areas of the sections or quarter-sections made “fractional” by the presence of the body of water.

The following quotation from the Manual indicates the location of meander lines, their functions in the survey, and their authority as boundaries.

“Lands bounded by waters are to be meandered at mean high-water mark. This term has been defined in a State decision (47 Iowa, 370) in substance as follows: High-water mark in the Mississippi River is to be determined from the river-bed; and that only is river-bed which the river occupies long enough to wrest it from vegetation.

“In another case (14 Penn. St. 59) a bank is defined as the continuous margin where vegetation ceases, and the shore is the sandy space between it and low-water mark.

“Numerous decisions in State and U. S. Supreme Courts assert the principle that meander lines are not boundaries defining the area of ownership of tracts adjacent to waters. The general rule is well set forth (10 Iowa, 549) by saying that in a navigable stream, as the Des Moines River in Iowa, high-water

mark is the boundary line. When by action of the water the river bed changes, high-water mark changes and ownership of adjoining land changes with it. The location of meander lines does not affect the question.

"Inasmuch as it is not practicable in public land surveys to meander in such a way as to follow and reproduce all the minute

FIG. 61. SHOWING THE RELATION OF MEANDER CORNERS AND MEANDER LINES TO THE SECTION LINES.

windings of the high-water line, the U. S. Supreme Court has given the principles governing the use and purpose of meandering shores, in its decision in a noted case (*R. R. Co. v. Schurmeier*, 7 Wallace, 286-7) as follows:

"In cases where the deputy finds it impossible to carry his meander line along mean high-water mark, his notes should state the distance therefrom, and the obstacles which justify the deviation.

"Proceeding down stream, the bank on the left hand is termed the left bank and that on the right hand the right bank. These

terms will be universally used to distinguish the two banks of a river or stream.

“Navigable rivers, as well as all rivers not embraced in the class denominated ‘navigable,’ the right-angle width of which is three chains and upwards, will be meandered on both banks, at the ordinary mean high-water mark, by taking the general courses and distances of their sinuosities, and the same will be entered in the field book. Rivers not classed as navigable will not be meandered above the point where the average right-angle width is less than three chains, except that streams which are less than three chains wide and which are so deep, swift, and dangerous as to be impassable through the agricultural season, may be meandered, where good agricultural lands along the shores require their separation into fractional lots for the benefit of settlers.”

× 167. **ACCESS TO RECORDS AND MAPS OF THE PUBLIC LANDS SURVEYS.**—It is evident that a present day surveyor, practicing in a region originally owned as Public Land and surveyed as such, should have frequent access to the field notes of the original survey of his district. The Circular previously referred to states that “The original evidences of the public land surveys in the following States have been transferred to the State authorities, to whom application should be made for such copies of the original plats and field notes as may be desired, viz.:

Alabama: Secretary of State, Montgomery.

Arkansas: Commissioner of State Lands, Little Rock.

Illinois: Auditor of State, Springfield.

Indiana: Auditor of State, Indianapolis.

Iowa: Secretary of State, Des Moines.

Kansas: Auditor of State and Register of State Lands, Topeka.

Michigan: Commissioner of State Land Office, Lansing.

Mississippi: Commissioner of State Lands, Jackson.

Missouri: Secretary of State, Jefferson City.

Nebraska: Commissioner of Public Lands and Buildings, Lincoln.

Ohio: Auditor of State, Columbus.

Wisconsin: Commissioners of Public Lands, Madison.

“In other public land States the original field notes and plats are retained in the offices of the United States Surveyors General.”

In many if not all these States named either the original records or copies of the same have been distributed among the various

Counties of the State, and are kept for reference and inspection in the office of the County Register of Deeds, County Surveyor, or other official.

Township maps of much of the area covered by the Public Lands Surveys may be obtained from the General Land Office at Washington, at nominal prices. ✓

168. RELOCATING LOST CORNERS. — It has been the common experience that many of the monuments and marks originally established on the lines of the Public Lands Surveys become lost or obliterated by the time the country has been settled for a generation or two. Witness and line trees * are cut down when the land is cleared, the pits and mounds marking the corners on the prairie are quickly destroyed when the sod is broken up, posts rot away, and no one takes the trouble to see that new and more durable marks are set to perpetuate the location of the points. Largely owing to the fact that in the areas covered by the Public Lands Surveys the public roads are usually located along the section lines, even substantial stone monuments oftentimes are carelessly knocked out of place and eventually are thrown into the ditch or the fence corner. Particularly during the pioneer period, when the country is just being settled and land is cheap, the greatest indifference prevails relative to the preservation of the original monuments, resulting in serious disputes and costly litigation later when the land becomes more valuable. A considerable part of the work of the present day County Surveyor is concerned with the relocation of corners that have been carelessly destroyed.

An act of Congress approved February 11, 1805, specifically provides that corners actually located in the field shall be established as the proper corners of the sections or quarter-sections which they were intended to designate, **irrespective of whether they were properly located in the first place or not.** A further

* "Line trees" are those directly on a line of the survey. They are blazed on opposite sides, the blazes facing backward and forward along the line. Trees near the line are scored with two blazes "quartering" toward the line; the further the trees are from the line the nearer together the two blazes are placed, and vice versa. These blazed trees are of great service in marking the approximate position of the line through the timber.

provision is that "the boundary lines actually run and marked" (in the field) "shall be established as the proper boundary lines of the sections, or subdivisions, for which they were intended, and the length of such lines as returned by . . . the surveyors aforesaid shall be held and considered as the true length thereof." These are the principles upon which is based the present practice in the relocation of the corners of the original survey.*

The General Land Office distinguishes between an **obliterated** and a **lost** corner, as follows:

"An **obliterated** corner is one where no visible evidence remains of the work of the original surveyor in establishing it. Its location may, however, have been preserved beyond all question by acts of landowners, and by the memory of those who knew and recollect the true situs of the original monument. In such cases it is not a **lost** corner.

"A **lost** corner is one whose position cannot be determined beyond reasonable doubt, either from original marks or reliable external evidence."

In the case of a corner that is merely obliterated the method of procedure, obviously, is to establish a new monument in the same location as the old one, this location being determined by the evidence presented, which should be adequate for the purpose. Instances of this kind occur when old witness trees, or their stumps, or the depressions left in the forest floor by their decay, may be identified; or when the point is marked by the intersection of hedge or stone or other permanent fences which admittedly were constructed on line when the monument was still in place; or when the "true situs of the monument" is testified to by other competent witnesses. (See Art. 151, p. 116.)

In the case of lost corners the true location must ordinarily be determined from data obtained by actually rerunning the old lines, as nearly as may be. But here, in accordance with the principle first stated above, the aim should be to relocate the

* The General Land Office publishes a Circular on the Restoration of Lost or Obliterated Corners and Subdivision of Sections, which states these principles and suggests methods of procedure in conformity therewith. Many of the methods referred to in the following paragraphs are condensed from this Circular.

corner at the exact point at which it was originally established, irrespective of whether it was properly located in the first place or not. As a help toward this end the following suggestions are offered, taken mainly from the Circular of the General Land Office to which reference was made in the earlier part of this Article.

A lost corner on a principal or guide meridian or range line will be located by proportional measurements from the nearest original corners in place north and south of the lost corner. It will be located on the straight line joining these original corners, irrespective of whether the measurements to corners east or west of the lost corner correspond with the original field notes or not.

A lost standard corner on a base-line or standard parallel or other correction line will be located by proportional measurements to the nearest original corners east and west of the lost corner, and will be located on the true line joining them, irrespective of whether the required distances to corners north or south would tend to pull it off this line or not. In like manner, a lost corner on an interior latitudinal township line will be recovered by proportional measurements to corners in place east and west of it.

In other words, **a lost corner is to be relocated by proportional measurements from corners which were established at the same time and with the same degree of care as the lost corner.** It sometimes happens that errors are discovered which throw a doubt upon the accuracy of the field notes of the line upon which the corner in question was located, in which case the lateral measurements might prevail and the corner be located in accordance with them; but ordinarily the rule as stated is the one to be observed.

A lost section corner in the interior of a township is to be located by proportional measurements from the corners nearest to it in all four directions. It is sometimes found, however, that the meridional section lines have been run with greater care than the latitudinal lines, owing to the operation of certain routine methods in use on some surveys. In case this is found to be true, the measurements on the meridional section lines may be given a certain precedence over those on the latitudinal lines.

A lost closing corner on a correction line should be located at

the intersection of the correction line with the meridional line closing upon it, even though the distance called for would place the corner north or south of the correction line. It is even held true of a closing corner actually in place, if it happens to be a little off the correction line, that such corner is to be construed as establishing merely the **direction** and not the **termination** of the meridional line upon which it is located. This is one of the very few cases in which the statutory provision quoted in the early part of this Article is not rigidly adhered to.

A lost quarter-section corner is always to be established at the middle point of the section line upon which it was originally located, except those next to the west and north boundaries of the township. On correction lines the quarter-section corners referring to the sections south of the line* are to be located midway between the adjacent closing section corners, except that in the north boundary of Section 6, which is to be placed forty chains west from the east boundary of the section.

169. Subdivision of Sections.—When the Public Lands were parceled out to settlers the quarter-section was usually the unit area granted as a "homestead." To locate the lines of a "quarter," however, obviously required the establishment of the quarter-section corner at the center of the section. Also, the subsequent division of the original "quarters" into "eighties," "forties," or other minor subdivisions has necessitated the location of numerous corners in addition to those originally established by the Government. Much of the routine work of the present day surveyor is in connection with subdivisions of this kind. In the following paragraphs a number of typical examples will be given, illustrating common practice in the location of subdivisional corners. It will be noted that the methods given are based upon those employed in the original surveys of the sections.

The interior quarter-section corner of a section is always to be located at the intersection of straight lines joining the quarter corners on opposite sides of the section. This method holds wherever the section may be located within the township; that is,

* It will be remembered that these corners were not established on the original survey.

it applies to those in the north and west tiers as well as to the other sections of the township. For example, the center of Section 19, in Fig. 61a, would be properly located at the intersection of *ab* and *ef*. This rule would still hold even though, through some error in the original fieldwork, the corner *f*, for instance, had been set too far east by one chain-length. If the corner is still in the place at which it was actually set by the Deputy Surveyor, this location is established for all time as the proper corner for the northern quarters of the section, and the line from *e* will be run to it.

FIG. 61a. ILLUSTRATING METHODS OF LOCATING INTERIOR QUARTER-SECTION CORNERS.

In case one or more of the exterior quarter-section corners are not accessible, lines are run through the interior of the section from whatever quarter corners are in place, having as nearly as possible the same directions as they would have were all the exterior corners actually in place, and the interior quarter-section corner is located at their intersection. For example, in Fig. 61a the corner at the center of Section 21 would be located by the intersection of a line run north from *d* in a direction which is a mean between that of *ED* and that of *FC*, with a line run east from *c* having a direction which is a mean between those of *CD* and *FE*. In case only one of the interior lines can be run, the corner may be established by proportionate measurements along that line. For example, the center of Section 20 would be located by measuring out from *c* on the line *cb* a distance equal to half the mean length of *CB* and *FG*. A modification of this method is required in the west and north tiers of sections

in a township. In the case of sections lying in the west tier the meridional line run from the quarter corner on the north or south boundary of the section is run parallel to the east line of the section; and similarly, in the case of sections lying in the north tier the latitudinal interior line initiated at the quarter corner on the east or west boundary is run parallel to the south line of the section. The reasons for this method of procedure in these special cases are easily apparent from a consideration of the methods previously described for the establishment of the original quarter-section corners in these sections.

For subdivisions smaller than quarter-sections the same general methods are employed. For example, to subdivide the north-east quarter of Section 10 (Fig. 61b) into quarter-quarters or

FIG. 61b. ILLUSTRATING THE SUBDIVISION OF A QUARTER OF AN INTERIOR SECTION.

NOTE. — Figures on the outside lines of the illustration are those of the original survey.

“forties,” straight lines are run connecting the middle points of the opposite sides of the quarter. In case one or more of these starting corners are inaccessible, the quarter will be subdivided by the application of methods similar to those just outlined for the location of the quarter-section corner at the center of a section. In the subdivision of quarter-sections adjacent to the west or

north boundaries of the township the excesses or deficiencies originally thrown into these quarters are not divided up between the different subdivisions, but are carried forward into the western or northern tiers of forty-acre lots. Fig. 61c illustrates this point by showing an ideal subdivision of the northwest quarter of Section 6, in a township not immediately south of a correction

FIG. 61c. SHOWING THE SUBDIVISION OF THE NORTH-WEST QUARTER OF SECTION 6.

NOTE.— Figures on the outside lines of the illustration are those of the original survey.

line. In order to make them apparent in the Figure, the original excesses and deficiencies are shown on an exaggerated scale. The tract marked A might be properly described as "the north-west quarter of the northwest quarter of Section 6," or simply as "Lot 4, of Section 6," of the appropriate township and range.

FIG. 62.

170. CONVERGENCE OF THE MERIDIANS. — The angular convergence of the meridians, given in Table 3, may be computed as follows. In Fig. 62 AB is an arc of a parallel of latitude and EQ the arc of the equator intercepted by the meridians through A and B . AT and BT are lines tangent to the meridians at A and B , meeting the earth's axis, prolonged, at T . It will be seen that the angle BTO equals the angle BOQ , which is the latitude of points A and B . The angle $AO'B$ is the difference in longitude of points A and B . The angle

between the meridians at A and B is the angle ATB .

In the sector $AO'B$,

$$\frac{AB}{BO'} = \text{angle } AO'B$$

In the sector ATB ,

$$\frac{AB}{BT} = \text{angle } ATB \text{ (approximately)}$$

But
$$BT = \frac{BO'}{\sin BTO'} = \frac{BO'}{\sin BOQ}$$

$$\begin{aligned} \therefore \text{angle } ATB &= \frac{AB}{BO'} \sin BOQ \\ &= \text{angle } AO'B \sin BOQ, \end{aligned}$$

i.e., the angular convergence equals the difference in longitude times the sine of the latitude.

The *linear* convergence of two meridians equals the distance run (N. or S.) times the sine of the angular convergence.

Example.—To find the angular convergence between two meridians 6 miles apart in latitude 37° . The length of 1° of longitude in latitude 37° is 55.30 miles (Table 7).

$$\frac{6}{55.30} \times \sin 37^\circ \times 60 = 3'.9.$$

TABLE 7.

LENGTH OF A DEGREE IN LONGITUDE.

Lat.	Degree of Longitude Statute Miles.	Lat.	Degree of Longitude Statute Miles.	Lat.	Degree of Longitude Statute Miles.

CHAPTER VI.

TRAVERSE LINES. — LOCATION OF BUILDINGS. — MISCELLANEOUS SURVEYING PROBLEMS.

TRAVERSE LINES.

171. TRAVERSES WHICH DO NOT FORM CLOSED FIGURES. —

A great many surveys, such, for example, as the preliminary surveys for railroads or pipe lines, call for traverses which do not return to the starting point. In this work the line is usually measured continuously from one end to the other, and the form of notes is commonly as follows. The starting point of the traverse is called "Station 0," the next station 100 ft. away is "Station 1," the next "Station 2," etc. Every 100-ft. length is a *full station* and any fractional distance is called the *plus*. The distance from Station 0 to any point, **measured along the traverse line**, is the station of that point and is recorded always by the number of the last station with the plus station in addition, e.g., the station of a point at 872.4 ft. from Station 0 is 8 + 72.4.

At the angle points it is customary to measure the **deflection angles** rather than the interior angles because the former are usually the smaller. These should be checked in the field by "doubling" the angles. (See Arts. 143-5, pp. 108-10.)

The notes are kept so as to read **up the page**. The left-hand page is for the traverse notes and the right-hand page for the sketch, the stations in the sketch being opposite the same station in the notes. Fig. 63 is a set of notes illustrating this type of traverse. Frequently no notes are kept in tabular form, all of the data being recorded on the sketch.

172. METHODS OF CHECKING TRAVERSES WHICH DO NOT FORM CLOSED FIGURES. — **Checking by Astronomical Methods.** —

The angles of any traverse can be checked by determining the azimuth of the first and last lines by astronomical methods. (See Chapter VII.) But since the meridians converge it is neces-

sary to make proper allowance for this convergence, the amount of which can be obtained from Table 3, p. 129.

173. Checking by Cut-Off Lines.—The angles may also be checked in some cases by cutting across from one point on the traverse to another at a considerable distance ahead, and measuring the angles from the traverse line at each end of this cut-off

(LEFT-HAND PAGE.)

(RIGHT-HAND PAGE.)

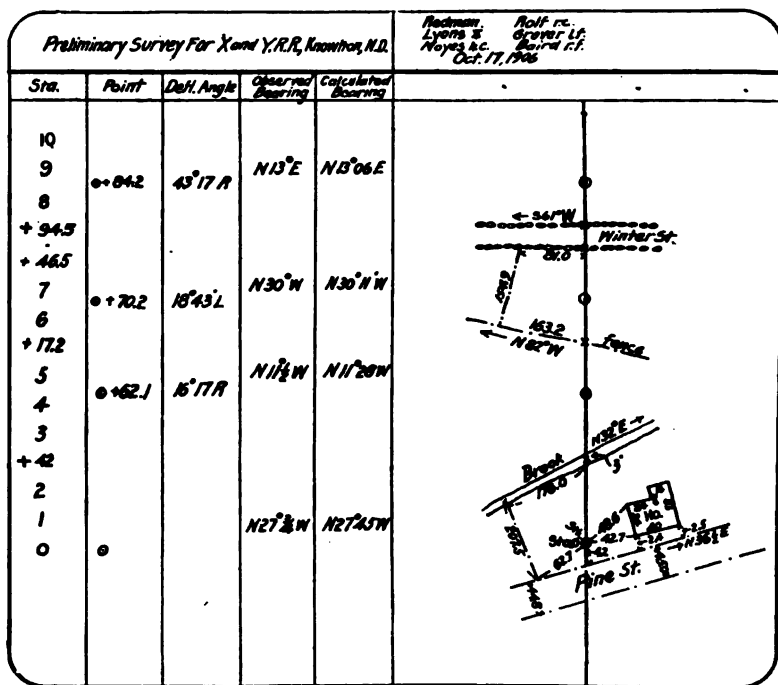

FIG. 63. TRAVERSE NOTES.

line, thereby obtaining all the angles of a closed traverse in which the length of one side only (the cut-off line) is missing. Sometimes the angle at only one end of the cut-off line can be measured, in which case the calculations for checking are not so simple as in the former case. When both angles have been measured the check consists in simply obtaining the algebraic sum of the deflection angles, while in the latter case the traverse must be computed.

174. Checking by Angles to a Distant Object.— A practical and very useful method of checking the azimuth of any line of the traverse is as follows. At intervals along the line, measure carefully the angle from the traverse line to some well-defined distant object, such as a distinct tree on a hill or the steeple of a church. If the survey is plotted and it is found by laying off the angles taken to the distant object that these lines do not meet at one point on the plan there is a mistake in the angles, and a study of the plot will show the approximate location of the mistake. If convenient, an angle to the distant object should be taken at every transit point. When plotted, if these lines meet at the same point in one section of the traverse and in another section meet at another point, then there is a mistake in the line which connects these two parts of the traverse. Frequently this distant point is so far away that it cannot be plotted on the plan. In this case as well as when it is desired to check more accurately than by plotting, the location of the distant point with reference to the traverse line can be computed by using these measured angles, as explained in Art. 408, p. 372. Plotting will not disclose minor errors of a few minutes only.

175. Checking by Connecting with Triangulation Points.— An accurate and practical method of checking both the angles and distances of a traverse is to connect the traverse with reliable *triangulation points* which can be easily identified. (See Art. 283, p. 255.) The latitude and longitude of these triangulation points and the distances between them can be obtained from the proper authorities. Sometimes the distances between them are not known but they can be computed. Then by connecting the traverse lines with these triangulation points by angles and distances a closed traverse is obtained, which serves as a good check.

Many surveyors fail to appreciate the value of this method of checking and do not realize how many such points are available. The information concerning such triangulation points can be obtained from The U. S. Coast and Geodetic Survey, The U. S. Geological Survey, State surveys, and frequently from City or Town surveys.

LOCATION OF BUILDINGS FROM TRANSIT LINE.

176. METHODS OF LOCATING BUILDINGS. — Many objects, such as buildings, are plotted directly from the survey line. In this case the measurements taken should be such as will permit the most accurate and rapid plotting. Sometimes where it is desirable to shorten the amount of fieldwork, the methods used are such as to gain time at the expense of accuracy or of simplicity in plotting. The accuracy with which such locations are made will depend upon the purpose of the survey. In city plans the accurate location of buildings is of great importance, while in topographic maps a rough location is often sufficient. There are so many different cases which will arise that this work requires considerable skill and judgment on the part of the surveyor.

177. GEOMETRIC PRINCIPLES. — Whether the locations are accurate or only rough, the principles involved are the same. In order to make clear the various methods used in the location of buildings it will be well to enumerate the geometric principles involved before giving particular cases occurring in practice.

A point may be located : —

- (1) By rectangular coördinates, i.e., by its station and perpendicular offset.
- (2) By two ties from known points.
- (3) By an angle and a distance from a known point.
- (4) By an angle at each of two known points.
- (5) By a perpendicular swing offset from a known line and a tie from a known point.
- (6) By perpendicular swing offsets from two known lines.

A line may be located : —

- (1) By two points on the line.
- (2) By one point on the line and the direction of the line.

178. TIES, OFFSETS, SWING OFFSETS, AND RANGE LINES. — In the above, the word *tie* is used as meaning a direct horizontal measurement between two points.

An *offset* is the distance from a line, usually at right angles.

A *swing offset* is the perpendicular distance to a line and is found by trial. The zero end of the tape is held at the point to be located and the tape is swung in a short arc about the point as a center, the tape being **pulled taut and kept horizontal**. The tape is read from the transit in various positions, and the shortest reading obtainable is the perpendicular distance desired.

A *range line* is a line produced to intersect the transit line or some other line.

179. GENERAL SUGGESTIONS. — By whatever method the buildings are located the following suggestions should be carried out.

(1) All the sides of the building should be measured and checked by comparing the lengths of opposite sides.

(2) Other things being equal, a long side of a building should be located in preference to a short side.

(3) Ties should intersect at an angle as near 90° as practicable, and never less than 30° .

(4) One or more *check measurements* should be taken in every case.

(5) In order to secure the best location the surveyor should keep constantly in mind how the building or other object which is being located is to be plotted.

In most work of this character it is customary to record the measurements to tenths of a foot. How precisely the measurements should be taken, however, depends upon the scale to which they are to be plotted.

180. TYPICAL CASES. — Although each case will have to be dealt with according to circumstances there are certain typical cases which will serve as guides. These are illustrated by the following examples.

181. Example I. Building Near Transit Line and Nearly Parallel to it. — As will be seen in Fig. 64 swing offsets are taken at the two front corners which, together with the tie from *A* to station 1 and the length of the front of the building locate points *A* and *B*. Then the general dimensions of the building are sufficient to plot and check the remaining sides. It is assumed that the corners of the building are square unless it is

obvious that they are not. The tie from *C* to station 2 is a check against an error in the other measurements.

PLOTTING.—This building would be plotted thus:—scale the distance *AX* perpendicular (estimated) to the transit line

FIG. 64.

and draw a line with triangles parallel to the transit line; then scale *A1* from station 1 to this parallel line. Point *A* is then located. Point *B* is located in the same way, *AB* being used as the tie from *A*. Then by means of triangles and scale the building is completed and the distance *C2* scaled and compared with the notes. Another way to plot point *A* would be to set on the compass the distance *1A* and swing an arc about 1 as a center; then, keeping the scale perpendicular to the transit line, find where the distance *XA* will cut this arc, thus locating point *A*. Point *B* can be similarly located after *A* has been plotted. For the same degree of accuracy distances can be measured more rapidly with a scale than they can be laid off with a compass, therefore the former method is usually more practicable.

This building might have been located by four ties *AO*, *A1*, *B1*, and *B2*. The plotting in this case would be slow because at least two of the ties must be swung by use of a compass, and inaccurate because the intersections would be bad.

182. Example II. Building Near Transit Line and Making a Slight Angle with it.—Fig. 65 illustrates two ways of locating a building in such a position that the intersection of the transit line by the long side (produced) can be readily obtained.

The left-hand building is located by the method of Example I. The tie *B1* could have been taken instead of *B2*. It would have given a better intersection at *B*, but since it is a longer tie than *B2* the fieldwork necessary is slightly greater. If *B2* is

taken $B1$ might be measured as a check tie although $A1$ would make a better check tie since it will also check the measurement of the side AB .

The right-hand figure illustrates another method of locating such a building. The front and side of the building are ranged out by eye, a method which is thoroughly practical and sufficiently precise for all ordinary purposes, and the plus stations of points E and F are measured. The range lines CE and DF are also measured and the check tie $C3$. $C2$ could have been taken as a check tie; it would have given a better intersection at C than the tie $C3$, but it is much longer.

FIG. 65.

PLOTTING. — The left-hand building is plotted as described in Example I. In plotting the right-hand building the plus stations on the transit line are first scaled. Then with the compass set at the distance EC an arc is swung from E as a center. From F the distance FC is scaled to intersect the arc, which locates point C and the direction of the side CD . The building is then plotted with triangles and scale. The check tie $C3$ should scale to agree with the notes and the line GC produced should strike point E .

There is little difference between these two methods in the amount of fieldwork, there being only one more measurement in the right-hand than in the left-hand figures, but one extra check is thereby obtained. In plotting, the method used in the right-hand figure is shorter.

183. Example III. Building Located Entirely by Direct Ties. — Any building not far from the transit line can be located and checked by four ties as in Fig. 66. This method has the advantage of being very simple and direct, especially in the field, but the plotting of the building calls for the use of the compass in two of the ties and hence is less rapid and accurate than where swing offsets or ranges can be used.

PLOTTING. — The plotting of this building is done by swinging the tie from one station to a corner of the building and scaling from the other station the tie to the same corner. Then the

FIG. 66.

other corner is plotted in the same way or by using the side of the building as one of the ties in case it gives a better intersection.

184. Example IV. Building Located at a Considerable Skew to the Transit Line. — A building which is at a considerable skew to the transit line can best be located by range ties as illustrated in Fig. 67. The range ties through *A* are sufficient to

FIG. 67.

locate the building, provided *AE* and *AF* are not too short in comparison with the sides of the building. If the seranges are long enough, then *B3* is a check tie; but if the ranges are short, *B3* must be depended upon to determine the position of point *B* and in this event one of the range ties becomes a check. But if *A* is within two or three feet of the transit line it will be well to omit one of the ranges and take the additional tie *AC* or the range tie *DC* produced.

PLOTTING. — If the ranges are of fair length the building is plotted as explained for the right-hand building in Art. 182, but if the range ties are short point B is located either by swinging the arc with radius EB and scaling $B3$ or by arc $3B$ and scaling EB . Then the direction of AB is determined and the building is plotted. CA produced should strike at F , and AF should scale the measured distance.

185. Example V. Buildings at a Long Distance from the Transit Line. — It is evident that in this case (Fig. 68) the tape

is not long enough to allow the use of swing offsets. Range ties may be used provided the building is not so far away that the eye cannot judge the range line with reasonable accuracy. Sometimes the only methods available are long ties or angles or a combination of the two. In any specific case there may be some objections to any of these methods, and the surveyor will have to decide according to circumstances which method he will use. For example, where there are obstacles to the measurement of ties, the corners of the building may have to be located entirely by angles from two points on the transit line. Location by angles is objectionable because it is difficult to plot an angle quickly and at the same time accurately. It often happens, however, that when a building is at a considerable distance from the transit line its accurate position is not required, since as a rule the features near the transit line are the important ones. This method of "cutting in" the corners of the building by angle is often used in rough topographic surveying and is decidedly the quickest of all methods so far as the fieldwork is concerned.

PLOTTING. — The angles are laid off from the transit line

with a protractor and the proper intersections determine the corners of the buildings. If the building is measured the side between the corners located will be a check tie.

In some cases, e.g., in making a topographic map on a small scale, the buildings are not measured at all, their corners being simply "cut in" by several angles from different transit points, and the shape of the building sketched in the notes.

186. Example VI. Buildings Located from Other Buildings.—

Buildings which cannot be conveniently located from the transit line on account of intervening buildings may be defined by ties from the ones already located. Fig. 69 shows several ways

FIG. 69.

in which such buildings may be located. Any of the preceding methods are applicable, using the side of the house as a base-line, but it will be found that range ties are almost always preferable. For example, the barn is located by the distance BK , the range tie KC and the tie BC , and checked by the tie BE . Another location of the barn is the distance AK or BK , the range tie KC , and the two range ties AJ and CJ . By this latter method the directions of both sides of the barn are checked. Still another location of the point C would be to substitute in the place of the range tie CK a swing offset from C to the house. The shed is located by the range ties AF and FG and by the tie AG . The check tie HD in general checks the location of both the barn and the shed. If the side HL is ranged out instead of the opposite side it will be seen that the tie AL will give a

poorer intersection at L . If convenient a tie from L to 4 or the range GF continued to the transit line may be measured as a check.

187. Example VII. Buildings of Irregular Shape.—Occasionally a building of irregular shape has to be located. For example, the shop in Fig. 70 is located on the front by ties and

FIG. 70.

swing offsets like Example I; then the direction of AB is determined by the range tie BC . The back corner E is determined by the ranges FH and EH , and by the dimensions of the building; FA is assumed parallel to GB . If the angle F is a right angle the tie EF may be taken instead of the range ties FH and EH , but even when F is a right angle it will be well if time will permit to take these range distances as they give valuable checks on the other measurements which the single tie EF does not furnish. ED is scaled along HE produced and the rest of the building plotted by its dimensions and checked by AD .

The ties shown on Fig. 70 to locate the factory chimney will locate its sides even if they do not form a regular polygon. If such a structure is situated at a considerable distance from the transit line probably the best way to locate it is by angles and distances to the corners, by the measurements of the sides, together with a few such ranges as NJ or KJ .

188. Example VIII. Large City Buildings.—Fig. 71 illustrates the location of several buildings in a city block where the transit line runs around the block. The fronts of the buildings are located from the transit line and the rear corners are tied together. The range ties are shown by dotted lines and other ties by dashes. The angles measured are marked by

arcs. At the curve AB , the side lines of the building are ranged out to point C which is located from the transit line by an angle

FIG. 71.

and distance and checked by a swing offset; CD is also measured to locate point D on the curve.

Frequently large buildings have their walls reinforced by pilasters, and care should be taken in such cases not to confuse the neat line of the wall with the line of the pilasters.

189. Example IX. Location of Buildings by Angles and Distances.—It will be seen from Figs. 71 and 72 that some of the buildings have been located by angles and distances from transit points. Any of the buildings in the above examples could be located by this method, and on account of the rapidity with which the work can be done in the **field** many surveyors prefer to use it almost exclusively.

190. Location of Buildings and Fences from Transit Line.—Fig. 72 is a sample page from a note-book illustrating the above principles. It will be noticed that in the field notes the letter R appears where the lines are ranges.

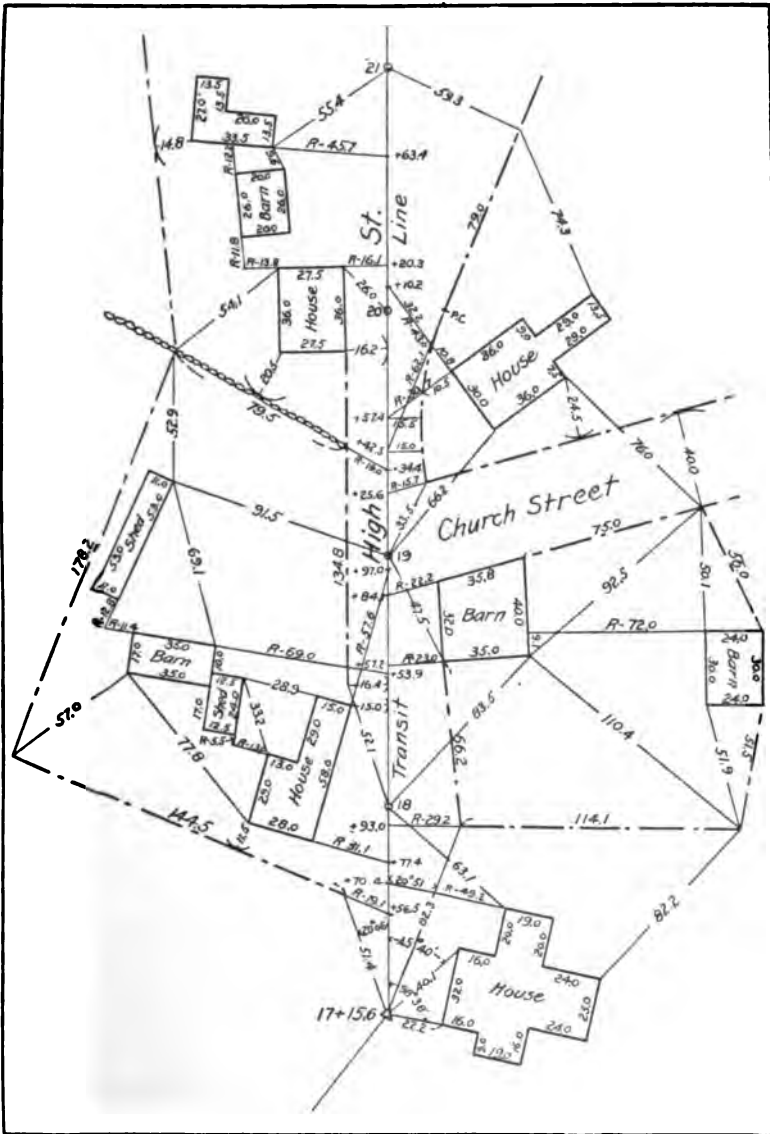

FIG. 72.

MISCELLANEOUS SURVEYING PROBLEMS.

191. RANDOM LINE. — Not infrequently in attempting to run a straight line between two points *A* and *B* (Fig. 73) it is impossible to see one point from the other or to see both points *A* and *B* from an intermediate set-up on a straight line between them. When this condition exists it is necessary to start at one point, e.g., *A*, and run what is called a trial, or *random*, line *AC* by the method explained in Art. 64, p. 52, in the direction of the other end of the line as nearly as can be judged.

Where the random line passes the point *B* the perpendicular offset *YB* is measured and also the distance to point *Y* along *AC*. Unless the random line is very close, say, within about two feet of the line *AB*, the point *Y* where a perpendicular to *AC* will pass through *B* cannot be accurately chosen by eye. The method resorted to in this case is one which has very general application in all kinds of surveying work, and is as follows.

FIG. 73.

With the transit at *A* point *X* is set carefully on the line *AC* and as nearly opposite point *B* as possible. Then the instrument is set up at *X* and 90° turned off in the direction *XZ*. If this line does not strike *B* (and it seldom will exactly) the distance *BZ* is carefully measured by a swing offset as described in Art. 178, p. 159. The distance *BZ* is equal to the distance *XY* which is added to *AX* giving the length of the long leg *AY* of the right triangle *AYB*. The distance *YB* is then measured, and *AB* and angle *YAB* are easily calculated.

Angle *DAY* has been measured from some previous course

The instrument is then set up at B and a right angle ABF laid off with the transit. BF is made any convenient distance which will bring the auxiliary line beyond the building. Similarly point E is set opposite point A , and sometimes a second point E' opposite A' , points A and A' being **exactly** on the transit line. These points E and E' need not be set by means of a transit set up at A and at A' unless AE is quite long.

The instrument is then set up at F and backsighted on E , the sight is checked on E' , the telescope inverted, and points G , H , and H' set on line. Leaving the telescope inverted, another backsight is taken on E , and the process repeated as described in Art. 64, p. 52. Then the transit is moved to point G , and a right angle turned off, and point C set on the right angle line, the distance GC being made equal to BF .

FIG. 74.

Then by setting up at C and sighting ahead on D , ($DH = GC$), and checking on point D' , ($D'H' = GC$), the transit line is again run forward in its original location. The distance FG is carefully measured which gives the distance BC , and thus it appears why it is so necessary that the lines BF and GC shall be laid off at right angles by means of the transit. The other offsets AE , $A'E'$, DH , and $D'H'$ are not in any way connected with the measurement along the line; they simply define the direction of the line so that if convenient it is often only necessary to show these distances as swing offsets for the transitman to sight on. From what has been said it will be seen that offsets $A'E'$ and $D'H'$ are not absolutely necessary, but they serve as desirable checks on the work and in first-class surveying they should not be omitted. For obvious reasons the offsets AE and DH should be taken as far back from the obstacle as is practicable.

Should the house be in a hollow so that it is possible to see over it with the instrument at A , the point D , or a foresight of some sort (Art. 64, p. 52) should be set on line beyond the house

to be used as a foresight when the transit is set up again on the original line. The distance may be obtained by an offset line around the house or by slope measurements to the ridgepole. Sometimes it is possible to place exactly on line on the ridgepole of the house a nail or a larger wooden sight which gives an excellent backsight when extending the line on the other side of the building.

If the building has a flat roof it may not be out of the question to set a point on the roof exactly on line, move the instrument to this point on the roof, and prolong the line in this way. Under these conditions the transitman will have to be extremely careful in the use of his instrument as it will be set up on an insecure foundation. If he walks around the transit he will find that it affects the level bubbles and the position of the line of sight; it is therefore well for him if possible to stand in the same tracks while he backsights and foresights. Sometimes two men, one in front and one behind the transit, can carry on the work under these conditions more accurately and conveniently. This method insures an accurate prolongation of the line, but the distance through the building must be measured by an offset method, unless it can be done by plumbing from the edge of the flat roof.

194. SHORT TRANSIT SIGHTS.— Sometimes the offset BF (Fig. 74) does not need to be more than 2 or 3 feet. The shorter this offset line can be made, and still clear the building, the better. But to lay off the short line BF will require a method somewhat different from any that has been heretofore explained. As the ordinary transit instrument cannot be focused on a point much less than about 5 ft. distant it is impossible to set point F directly. The method employed is to set a temporary point, say 10 ft. distant, on which the transit can be focused, and on a line perpendicular to the original transit line. From the transit point to this auxiliary point a piece of string may be stretched and the point F set at the required distance from B and directly under the string.

195. Bisection Method.— A method which is economical in fieldwork but not very accurate is the following. In Fig. 75 the instrument is set up at A , backsighted on the transit line, and equal angles turned off on each side of the transit line pro-

duced. Points B' and C' are carefully set on one of these lines and at convenient distances from A , and on the other line points

FIG. 75.

B'' and C'' are set at the same distances from A . Then point B is placed midway between B' and B'' , and similarly point C is set midway between C' and C'' . The line BC is the prolongation of the transit line. Of course the distance $B'C'$ should be made as long as practicable. The inaccuracy in this method lies entirely in laying off the two angles. (See Art. 61, p. 50.)

In this case the distance AB can be computed from the formula

$$AB' - AB = \frac{BB'^2}{2AB} \text{ (approximately). (See foot-note, p. 13.)}$$

196. **Measuring Around a Small Obstacle.**—In Fig. 76 the

FIG. 76.

line AB runs through a tree, and points A , D , and B have been set on line. DE is made equal to some convenient short distance and laid off at right angles to the transit line by eye. Then AE and EB are measured. The distance

$$AB = AE - \frac{DE^2}{2AE} + EB - \frac{DE^2}{2EB}. \text{ (See foot-note, p. 13.)}$$

When DE is taken as some whole number of feet the computation of the above is extremely simple.

This method of measuring around a small obstacle might be applied much more generally than it is at present if its accuracy and its simplicity were more fully realized by surveyors.

197. Equilateral Triangle Method.—While this method requires much less fieldwork than the offset method described above it is at the same time less accurate. Point B (Fig. 77) is set on the transit line as near the building as practicable but so that a line BC at 60° with the transit line can be run out. The instrument is set up at B , backsighted on A , and an angle of 120° laid off; the line BC is made long enough so that when the instrument is set up at C and 60° is laid off from it, CD will fall outside the building. BC is measured and CD is made equal to BC . If the instrument is set up at D and angle CDE laid off equal to 120° the line DE is the continuation of the original transit line,

FIG. 77.

and the line $BD = BC$. This method is subject in three places to the errors incident to laying off angles and, when BC and CD are small, it has in two of its intermediate steps the disadvantages due to producing a short line.

198. INACCESSIBLE DISTANCES.—If the obstruction is a pond, points on the far side of it can be set and these should be used in producing the transit line. When the line can be produced across the obstacles the following methods may be used.

199. Inaccessible Distance by Right Triangle Method.—In Fig. 78 the line AB is made any convenient length and at any convenient angle to the transit line. The line BC is laid off at 90° to BA and is intersected with the transit line and the distance BC measured. AC is calculated from AB and $\cos A$ and checked by BC and $\sin A$. Also the angle ACB can be measured which will check the transit work.

FIG. 78.

200. INTERSECTING TRANSIT LINES.— In many kinds of surveying work it is necessary to put in points at the intersection of two transit lines. It would be an easy matter to set the point if two transits could be used, one on each line, and the sight simultaneously given by each transitman. As it is seldom practicable to use more than one transit in a surveying party the following method is resorted to.

An estimate is made by eye where the lines will cross each other and temporary points not more than 10 ft. apart are set on one of the transit lines by means of the instrument, enough points being marked to make sure that the second line will cross somewhere among this set of temporary points. A string is then used to connect two of these temporary points and the transit is set up on the other transit line and the point where the second line cuts the string is the intersection point. Sometimes when the lines cross each other at nearly 90° the intersection point can be estimated so closely that only two temporary points need be placed on the first line. In other cases, where the two transit lines cross at a very small angle, it is impossible to tell by eye within several feet where the lines will intersect and a number of points must be used because in practice the stretching line is seldom applicable for distances much over 15 ft. For short distances the plumb-line can be used as a stretching line.

201. Inaccessible Distance by Swing Offset Method.— If the distance across a pond or river is not great the following method

may be used. It has the advantage of requiring the minimum amount of fieldwork. With the instrument at *A* (Fig. 79) point *C* is set on the transit line on the far side of the river. The instrument is then set up at *C* and the angle ACB measured between the transit line and a 100-ft. swing offset from point *A*.

A pencil is held vertically at the 100-ft. mark of the tape and while the zero point is held firmly at *A* the tape, which is constantly kept horizontal and taut, is swung slowly in an arc *ab*. The transitman, using the tangent screw, can follow the pencil with the vertical cross-hair of the transit, stopping the cross-hair when the pencil is in its farthest position

FIG. 79.

from *A*. Then as the tape is swung the second time he can check his setting and when this is established the angle ACB is read. The distance AC then is very easily calculated. It should be noted, however, that if AC is several times as long as AB the resulting error in AC may be so great as to prohibit the use of this method where very precise results are required. There is no reason why the swing offset could not be made at *C* with the instrument at *A* if more convenient.

202. Inaccessible Distance by Tangent Offset Method. — In the method described above the distance across the pond may be so great that 100 ft. will be too short a base to use, or point *A* may be situated on ground sloping upward towards *B* so that a swing offset

cannot be made. In such cases the line AB (Fig. 80) can be laid off at right angles to the transit line and of any convenient length.

FIG. 80.

Then the angle ACB is measured and the line AC computed. By another set-up of the instrument the angle B can be measured as a check, and if the line BC does not cut across the pond its length can also be measured as a further check.

203. Inaccessible Distance by Oblique Triangle Method. — Often the shores of a stream are covered with trees so that none

FIG. 81.

of the above methods are applicable. It may be convenient to measure a line AB (Fig. 81) in but one direction along the shore. In this case the point C is first carefully set on the opposite side, the line AB measured along the shore, and the angles at A and

at C are measured. The distance AC can then be computed. It will be well also to set up at B and measure the angle B as a check on the work. At the time when point C is set it is also good practice to set a point further ahead on the line, to use as a foresight to check the transit line when the instrument is moved across the river.

204. To Obtain the Distance Between Two Inaccessible Points by Observation from Two Accessible Points.—In Fig. 82 the points A and B are inaccessible and it is desired to obtain the distance AB and the angle that AB makes with the transit line. From the point D the distance DC and the angles BDA and ADC are measured, and similarly at C the angles ACB and BCD are measured. AB can then be calculated as follows:—in the triangle CBD compute CB ; in triangle ACD compute AC ; and in the triangle ACB calculate AB , the inaccessible distance. In the tri-

FIG. 82.

angle ACB , angle ABC can be computed, which, together with the measured angle BCD , will give the difference in direction between AB and CD . It is not at all necessary that DC should have been measured as one straight line in the traverse; the traverse might have run as indicated by the dotted lines, but in such an event the distance CD and the necessary angles could have been easily figured so that it could be reduced to the above problem.

This problem occurs when the distance between two triangulation stations, A and B , and the azimuth of AB are desired and when it is inconvenient or impossible to measure the line AB or to occupy the points with the transit.

205. To Obtain the Inaccessible Distance Between Two Accessible Points by Observations on Two Inaccessible Points of Known Distance Apart. — In this case (Fig. 82) A and B are the two accessible points and C and D are the two inaccessible points but the distance DC is known; the distance AB is required. With the transit at A , the angles CAD and DAB are measured; at B the angle CBD and ABC are measured. The length of the line CD is known. While it is simple to obtain CD in terms of AB , it is not easy to directly determine AB in terms of CD ; it will be well therefore to use an indirect method. Assume AB as unity. Then by the same process as described in the preceding problem the length of CD can be readily found. This establishes a ratio between the lengths of the lines AB and CD , and the actual length of CD being known the distance AB can be computed.

A problem of this sort would occur under the following circumstances. If the distance CD between two church spires were accurately known (from a triangulation system) and it is desired to use this line CD as a base-line for a survey, two points A and B could be assumed, and the distance between them and the azimuth of AB could be found by this method.

CHAPTER VII.

OBSERVATIONS FOR MERIDIAN AND LATITUDE.*

OBSERVATIONS FOR MERIDIAN.

206. TO ESTABLISH A TRUE MERIDIAN LINE BY OBSERVATION ON POLARIS WITH THE TRANSIT. — On account of the earth's daily rotation on its axis all heavenly bodies **appear** to revolve once a day around the earth. Stars in the south appear to

FIG. 83.

revolve in large circles parallel to the daily path of the sun. As we look farther north the apparent size of the circles grows smaller. The center of these circles is the *north pole* of the *celestial sphere*, a point in the sky in the prolongation of the earth's axis. The pole-star (*Polaris*) revolves about the pole in a small circle whose radius is less than a degree and a quarter (Fig. 83). This angular distance from the pole to a star is called its *polar distance*.

When the star is directly above the pole its bearing is the same as that of the pole itself and the star is said to be at *upper culmination*. At this instant it is in the **true meridian**. About twelve hours later it will be below the pole at *lower culmination* and will be again in the true meridian. About half-way between these two positions the star reaches its greatest east or west bearing,

* See also Chapter II, Volume II.

and at such times is said to be at its greatest *elongation*. At either *eastern* or *western elongation* the star's bearing is not changing perceptibly because it is moving almost vertically, a

FIG. 84. RELATIVE POSITION OF THE CONSTELLATIONS NEAR THE NORTH POLE.

condition which is most favorable for an accurate observation. At culmination the star is changing its bearing at the maximum rate, and therefore this is not as good a time to make an accurate observation as at elongation. This star moves so slowly, however, that even at culmination its bearing can be obtained with sufficient accuracy for determining the declination of the needle. Polaris can be easily found by means of two conspicuous constellations near it, *Cassiopeia* and *Ursa Major*. The seven most conspicuous stars of the latter form what is commonly known as the "*Great Dipper*" (Fig. 84). The two stars forming the part of the bowl of the Dipper farthest from the handle are called the "*pointers*" because a line through them points almost directly at the pole. On the opposite side of Polaris is *Cassiopeia*, shaped like the letter W. A line drawn from δ^* *Cassiopeia*, the lower left-hand star of the W, to ζ *Ursæ Majoris*, the middle star of the Dipper handle, passes very close to Polaris and also to the pole itself.

207. **OBSERVATION FOR MERIDIAN ON POLARIS AT ELONGATION.** — When the Dipper is on the **right** and *Cassiopeia* on the **left**, Polaris is near its **western elongation**; when the dipper is on the **left** Polaris is near **eastern elongation**. When the constellations are approaching one of these positions the transit should be set over a stake and leveled, and the telescope focused upon the star.† Unless the observation occurs at about sunrise or sunset it will be necessary to use an artificial light to make the cross-hairs visible. If the transit is not provided with a special reflector for throwing light down the tube a good substitute may be made by cutting a small hole in a piece of tracing cloth or oiled paper and then fastening it over the end of the telescope tube by a rubber band. If a lantern is then held in front and a little to one side of the telescope the cross-hairs can be plainly seen. The star should be bisected by the vertical wire and followed by means of the tangent screw in its horizontal motion until it no

* The Greek Alphabet will be found on p. 516

† It is difficult to find a star in the field of view unless the telescope is focused for a very distant object. The surveyor will find it a convenience if he marks on the telescope tube the position of the objective tube when it is focused for a distant object.

longer changes its bearing but moves vertically. (It will be seen from Fig. 83 that when the star is approaching eastern elongation it is moving **eastward** and **upward**; when approaching western elongation it is moving **westward** and **downward**.) As soon as this position is reached the telescope should be lowered and a point set in line with the vertical cross-hair at a distance of several hundred feet from the transit. Everything should be arranged beforehand so that this can be done quickly. Immediately after setting this point the instrument should be reversed and again pointed on the star. A second point is then set at one side of the first. The mean of these two points is free from the errors of adjustment of the transit. If the instrument is in adjustment, of course, the first and second points coincide. On account of the great difference in altitude between the star and the mark the elimination of instrumental errors is of unusual importance (Art. 79, p. 61). For 10 minutes of time on either side of elongation the bearing of the star does not change more than 5 seconds of arc and therefore there is sufficient time to make these two pointings accurately.

After the direction of the star at elongation has been found, the meridian may be established by laying off an angle equal to the azimuth, or true bearing of the star. Since this angle to be laid off is the **horizontal** angle between the star and the pole, it is not equal to the polar distance but may be found from the equation:—

$$\sin \text{Star's True Bearing} = \frac{\sin \text{Polar Distance of Star}}{\cos \text{Latitude}} \quad *$$

The mean polar distances for the years 1906 to 1920 may be

* This equation may be derived as follows; in Fig. 83, let P represent the pole, Z the zenith, and E the position of the star at elongation. Then by spherical trigonometry,

$$\frac{\sin PZE}{\sin ZEP} = \frac{\sin PE}{\sin ZP}$$

But PZE is the angle between the two vertical circles and equals the bearing. $ZEP = 90^\circ$ because ZE is tangent to the circle $WUEL$, which represents the path of Polaris. PE is the polar distance and ZP may be shown to be equal to $90^\circ - \text{latitude}$.

Hence,

$$\sin PZE = \frac{\sin PE}{\cos \text{lat.}}$$

TABLE 8.

MEAN POLAR DISTANCES OF POLARIS.*

Year.	Mean Polar Distance.			Year.	Mean Polar Distance.		
	°	'	"		°	'	"
1906	1	11	41.05	1914	1	09	12.07
1907	1	11	22.37	1915	1	08	53.51
1908	1	11	03.71	1916	1	08	34.97
1909	1	10	45.07	1917	1	08	16.45
1910	1	10	26.44	1918	1	07	57.94
1911	1	10	07.82	1919	1	07	39.45
1912	1	09	49.22	1920	1	07	20.98
1913	1	09	30.64				

found in Table 8. The latitude may be obtained from a reliable map or by observation (Arts. 216-17, p. 196).

When the transit is set up at the south end of the line the angle thus computed must be laid off to the **right** if the elongation is **west**, to the **left** if the elongation is **east**. A convenient and accurate way of laying off the angle is by measuring the distance between the two stakes *A* and *B* (Fig. 85), and calculating the perpendicular distance *BC* which must be laid off at the north stake *B* to give a meridian *AC*.

FIG. 85.

* The above table was derived from data furnished by the Superintendent of the United States Coast and Geodetic Survey. The Mean Polar Distance is the average value of the polar distance for the entire year.

In taking the polar distance from the table for the purpose of looking up its sine the student should keep in mind the degree of precision desired in the computed azimuth. If the azimuth is to be within about one minute of the true value the polar distance need be taken only to the nearest minute, but if the azimuth is to be correct within a few seconds the polar distance should be taken to the nearest second. It should be noted however that since the values given in the table are only the average values for the year there will in general be an error of a few seconds due to neglecting the variation of the polar distance during the year. The exact value for every day in the year may be found in the "American Ephemeris and Nautical Almanac," published by the Bureau of Equipment, Navy Department.

TP 234 208. **OBSERVATION FOR MERIDIAN ON POLARIS AT CULMINATION.** — At the instant when Polaris is above the pole the star ζ *Ursæ Majoris* will be almost exactly underneath Polaris. When Polaris is below the pole δ *Cassiopeiæ* will be almost directly below Polaris (Fig. 84). In order to know the instant when Polaris is exactly on the meridian it is necessary first to observe the instant when one of these two stars is vertically below Polaris. From this the time when Polaris will be on the meridian can be calculated by adding a certain interval of time, and the meridian line can thus be directly established. This interval of time was, for ζ *Ursæ Majoris*, about $2^m 36^s$ in the year 1900, and it increases about 21^s per year. The intervals computed by this rule are only approximate, but are sufficiently accurate for many purposes and, as the change is very slow, the rule is good for many years. It may also be used for any latitude in the United States. When ζ *Ursæ Majoris* cannot be used, as is the case in the spring of the year, especially in northern latitudes, a similar observation can be made on δ *Cassiopeiæ*. The interval for this star was $3^m 24^s$ for 1900, with an annual increase of about 20^s .

The observation to determine when the two stars are in the same vertical plane is at best only approximate, since the instrument must be pointed first at one star and then at the other; but since Polaris changes its azimuth only about 1 minute of angle in 2 minutes of time, there is no difficulty in getting fair results by this method. The vertical hair should first be set on Polaris, then the telescope lowered to the approximate altitude of the other star to be used. As soon as this star comes into the field the vertical hair is again set carefully on Polaris. As it will take the other star about 2 minutes to reach the center of the field there will be ample time for this pointing. Then the telescope is lowered and the instant when the star passes the vertical hair is observed by a watch. This will be the time desired, with an error of only a very few seconds. The time of culmination should then be computed as described above and the vertical hair set on Polaris when this computed time arrives. The telescope is then in the meridian which may be marked on the ground.

It will be seen that in this method the actual error of the watch has no effect on the result since it is used only for measuring the interval of a few minutes. The error in the meridian obtained by this method will seldom exceed one minute of angle.

²³ 209. To Find the Standard Time of Culmination and Elongation. — The approximate times of culmination and elongation of Polaris for the 1st and 15th of each month in the year 1907 may be found in Table 9.

To find the time for any other date interpolate between the values given in the table, the daily change being about 4 minutes.

In order to find the exact time of culmination or elongation for any observation it would be necessary to take into account the latitude and longitude of the place and the exact date of the observation. The times given in Table 9 are only approximate in any case and are to be regarded merely as a guide so that the surveyor may know when to prepare for his observations.

The times are computed for mean local astronomical time at the 90th meridian west of Greenwich and for the year 1907. These numbers increase about $\frac{1}{3}$ minute each year so that this table may be used to obtain approximate results for subsequent years. Astronomical time begins at noon of the civil day of the same date and is reckoned from 0^h to 24^h, e.g., 18^h would mean 6^h A.M. The tabular numbers are nearly correct for the Standard Meridians, i.e., the 75th, 90th, 105th, and 120th west of Greenwich. All watches keeping "railroad time," or "standard time," are set to the local mean time of one of these four meridians (Art. 86, p. 68). To find the watch time of culmination or elongation for any other meridian, first find the difference in longitude in degrees between the place of observation and the standard meridian, and then convert this into minutes and seconds of time by dividing by 15, since 15° of longitude are equivalent to one hour of time. The standard, or watch, time of the observation is then obtained by **adding** this correction to the time taken from the table if the place is **west** or by **subtracting** it if the place is **east** of the standard meridian.

§ 36210. MERIDIAN OBSERVATIONS ON POLARIS WITH THE COMPASS.—In determining a meridian with the compass the observations are made as described for the transit except that the following modifications will be necessary. Suspend a long plumb-line a few feet away from the point where the instrument is to be set. Since the rear sight is the only part of the compass to be used in the observation it may be unscrewed from the compass and fastened to a piece of board. This board should be placed on a table. The compass sight may then be shifted to the right or left to bring it in line with the star and the plumb-line. The plumb-line should be illuminated by means of a lantern. The direction of the star may be marked by setting stakes in line. If the observation is made at elongation the

meridian should be laid out as described in Art. 207. In finding the declination of the needle the compass is set up over one of the meridian stakes and sighted at the other, when the declination can be read off directly. In order to obtain as nearly as possible the mean value of the declination this should be done at about 10 A.M. or 5 to 6 P.M. because at these times the needle is in its mean position for the day.

211. MERIDIAN OBSERVATION ON POLARIS AT ANY TIME WITH THE TRANSIT. — In order to make this observation, it is necessary to know the local time very closely. As in most cases the time which the surveyor carries is "standard time" it is assumed that such is the case here. The observation itself consists in either marking the direction of the star, as previously described, and noting the time by the watch when the star is sighted; or in repeating the angle between the star and some reference mark, the time of each pointing on the star being noted. In the latter case, take the average of the observed times and assume that it corresponds to the average angle. This is very nearly true if the observations extend over a few minutes of time only.

After finding the standard time of the observation, the next step is to compute the *hour angle* of the star at the time of the observation. Take from the Nautical Almanac: (1) the *right ascension* of Polaris for the date; (2) the *right ascension* of the "mean sun" for the date; (3) the *increase* in the *sun's right ascension* since Greenwich noon, which is found in Table III in the Appendix to the Nautical Almanac. Remember that the dates in the Almanac are in Astronomical time (Art. 209, p. 186). Reduce the standard time to local time by adding or subtracting the difference in longitude expressed in hours, minutes, and seconds, remembering that if the place is west of the standard meridian the local time is earlier than standard time and *vice versa*. To the local time add the sun's right ascension and the correction from Table III, Appendix, Nautical Almanac. The result is the *sidereal time*. From this subtract the star's right ascension, and the result is the hour angle of the star reckoned from the meridian from 0^h to 24^h in the direction of the star's apparent motion. Convert this angle into degrees, minutes, and seconds. The azimuth of the star may now be computed from the formula,

$$\tan Z = \frac{\sin t}{\cos L \tan D - \sin L \cos t}$$

where Z = the azimuth, or true bearing; t = the hour angle; L = the latitude; D = the declination = 90° — the polar distance. If the hour angle is between 0^h and 12^h the star is west of the meridian; if between 12^h and 24^h it is east of the meridian (see Example below).

In the "Manual of Surveying Instruction" issued by the General Land Office a set of tables is given which will enable the surveyor to perform all of the above work by simple inspection and without the aid of the Nautical Almanac.

* See Hayford's Geodetic Astronomy, p. 211, Art. 193.

EXAMPLE.

Observation on Polaris for azimuth April 15, 1908. Latitude $38^{\circ} 58'$. Longitude $92^{\circ} 25'$. Angle between a mark (approximately N.W.) and Polaris is repeated 6 times. Watch $1^m 13^s$ fast. The times are

* The * after the logarithm indicates that the number corresponding is negative.

212. SOLAR OBSERVATIONS. — Where great accuracy is not required many surveyors prefer solar observations because they can be made without much additional work, while star observations have to be made at night and require special arrangements for illuminating the field of view and the mark. If it is sufficient for the purpose in view to obtain the azimuth within $\frac{1}{2}$ minute of angle solar observations will answer. In making these observations with the ordinary transit it is necessary to have some means of cutting down the sun's light so that it will not be too bright for the eye while making pointings. This is usually effected by placing a dark glass over the eyepiece. A dark glass in front of the objective will introduce error into the pointings unless the faces of this glass have been made plane and exactly parallel. If the instrument is not provided with a dark glass the observation may be made by holding a white card back of the eyepiece while the telescope is pointing at the sun. If the eyepiece tube is drawn out the sun's disc and the cross-hairs can both be sharply focused on the card. By this means pointings can be made almost as well as by direct observation. It is also well to cut down the amount of light entering the objective by having a cap with a hole in the center or by using a piece of tracing cloth as explained in Art. 207, p. 182.

213. OBSERVATION FOR MERIDIAN BY EQUAL ALTITUDES OF THE SUN IN THE FORENOON AND AFTERNOON. — This observation consists in measuring in the forenoon the horizontal angle between the sun and some reference mark at the instant when the sun has a certain altitude, and again measuring the angle when the sun has an **equal** altitude in the afternoon. If the distance of the sun from the equator were the same in the two cases the horizontal angles between the sun and the meridian would be the same in both observations, hence the mean of the two readings of the horizontal circle would be the reading for the meridian. But since the sun is changing its distance from the equator the measured angles must be corrected accordingly. The correction is computed by the equation

$$X = \frac{d}{\cos L \sin t}$$

in which X = the correction to the mean vernier reading, d = the hourly change in declination of the sun taken from Table 10 and multiplied by half the number of hours between the two observations, L = the latitude, and t = half the elapsed time converted into degrees, minutes, and seconds. Since the hourly change for any given day is nearly the same year after year an almanac is not necessary but the table given below is sufficient.

TABLE 10.

HOURLY CHANGE IN THE SUN'S DECLINATION.

The observation is made as follows:— * at some time in the forenoon, preferably not later than 9 o'clock, the instrument is set up at one end of the line the azimuth of which is to be found, and one vernier is set at 0° . The vertical cross-hair is then sighted at the other end of the line and the lower plate clamped. The upper clamp is loosened and the telescope turned until the sun can be seen in the field of view. The horizontal cross-hair is to be set on the **lower** edge of the sun and the vertical cross-hair on the **left** edge. Since the sun is rising and also changing its bearing it is difficult to set both of the cross-hairs at once and it will be found easier to set the horizontal hair so that it will cut across the sun's disc leaving it clamped in this position while the vertical hair is kept tangent to the left edge of the sun by means of the upper tangent screw. When the sun has risen until the lower edge is on the horizontal hair

* The nearer the sun is due East or due West, the better the result.

the instrument is in the desired position and after this position is reached the upper tangent screw should not be moved. As soon as this position is reached the time is noted. Both the vertical and the horizontal circles should now be read and the angles recorded.

In the afternoon, when the sun is found to be nearly at the same altitude as at the forenoon observation, the instrument should be set up at the same point and again sighted on the mark. The observation described above is repeated, the pointings now being made on the lower and right edges of the disc. The telescope is inclined until the vernier of the vertical circle reads the same as it did at the forenoon observation. When the sun comes into the field the vertical hair is set on the right edge and kept there until the lower edge is in contact with the horizontal hair. The time is again noted and the verniers are read. If desired, the accuracy may be increased by taking several pairs of observations. The mean of the two circle readings (supposing the graduations to be numbered from 0° to 360° in a clockwise direction) is now to be corrected for the sun's change in declination. The correction as obtained by the formula given on p. 190 is to be added to the mean vernier reading if d is minus, and subtracted if d is plus, i.e., if the sun is going south the mean vernier reading is east of the south point, and *vice versa*. When the circle reading of the south point is known the true bearing of the mark becomes known and the bearings of other points may be found (see Example below).

The disadvantage of this method is that it is necessary to be at the same place both in the forenoon and afternoon, whereas in many cases the surveyor might in the afternoon be a long distance from where he was working in the forenoon.

EXAMPLE.

Latitude $42^{\circ} 18' N.$ April 19, 1906.

214. OBSERVATION FOR MERIDIAN BY A SINGLE ALTITUDE OF THE SUN.—The azimuth of a line may be obtained by measuring a single altitude of the sun with the transit and computing the azimuth by spherical trigonometry. The instrument is set at 0° and pointed at a mark. The upper clamp is loosened and pointings made as follows. First, the cross-hairs are set on the **left** and **lower** limbs of the sun and both circles are read; the time is also noted. If desired several sets of observations may be made. Second, the cross-hairs are set on the **right** and **upper** limbs, and the reading of the circles and the time are again recorded. The mean of the vertical circle readings is taken, and corrected for atmospheric refraction by subtracting the correction given in Table 11. This corrected mean is called h in the formula given below.

TABLE 11.

REFRACTION CORRECTION.

Altitude.	Refraction.	Altitude.	Refraction.
10°	5' 19''	20°	2' 39''
11	4 51	25	2 04
12	4 27	30	1 41
13	4 07	35	1 23
14	3 49	40	1 09
15	3 34	45	0 58
16	3 20	50	0 49
17	3 08	60	0 34
18	2 57	70	0 21
19	2 48	80	0 10

In order to compute the azimuth it is necessary to know the latitude of the place. This may be obtained from a reliable map or from an observation as described in Art. 216, p. 196. It is also necessary to know the declination of the sun at the instant of the observation; this is found as described in Art. 86, p. 68. If Z represents the azimuth of the sun's center from the south; L , the latitude; h , the altitude; p , the distance from the north pole to the sun (or 90° -declination); and $s = \frac{1}{2} (L + h + p)$; then

$$\cot^2 \frac{1}{2} Z = \frac{\sin (s - L) \sin (s - h)}{\cos s \cos (s - p)}$$

Five place logarithms will give the value of Z within 10 seconds of angle, which is amply accurate for this observation.

When the true bearing of the sun is known the bearing of the mark from the instrument can be found.

215. OBSERVATION FOR MERIDIAN BY MEANS OF THE SOLAR ATTACHMENT. — This observation has been described in detail in Art. 85, p. 66.

* See Art. 86, p. 68.

OBSERVATIONS FOR LATITUDE.

216. (1) BY THE ALTITUDE OF POLARIS AT UPPER OR LOWER CULMINATION. — When Polaris is approaching either culmination (see Art. 206, p. 180, and Fig. 83) set up the transit and point the horizontal hair on the star. Keep the cross-hair pointed on the star until the culmination is reached. Read the vertical arc and determine the index correction. The altitude is to be corrected for refraction by Table 11, p. 193. This gives the true altitude. If Polaris is at upper culmination subtract from the true altitude the polar distance of the star at the date of the observation (Table 8, p. 184). If the star is at lower culmination the polar distance is to be added. The result is the latitude of the place of observation.

217. (2). BY THE ALTITUDE OF THE SUN AT NOON. — The observation consists in finding the greatest altitude of the sun's lower limb. This will occur when the sun is on the meridian (very nearly). Begin the observation a little before *apparent* noon, remembering that this differs sometimes more than 16^m from *mean* noon.* Furthermore it should be remembered that standard time may differ a half hour or so from *mean* time. When the maximum altitude is found the following corrections are to be made: first, the refraction correction is to be subtracted (Table 11, p. 193); second, the sun's semi-diameter (found in the Nautical Almanac) is to be added; third, the sun's declination is to be subtracted if plus or added if minus. The result, subtracted from 90°, is the latitude.

* *Apparent* noon occurs when the sun is on the meridian. *Mean* noon is the instant when the sun would be on the meridian if it moved at a uniform rate along the equator. The difference between the two is known as the *Equation of time* and may be found in the Nautical Almanac. For example, on November 1st, the sun passes the meridian 16^m 18^s before *mean* noon, i.e., when it is 12^h 00^m 00^s *apparent* time it is 11^h 43^m 42^s *mean* time.

	<hr/> 47° 39'.3	Longitude = 4h 44m 18s W.
Latitude	42° 20'.7	= 4h.74
		Diff. 1h = + 19".58
		+ 19".58 × 4h.74 = + 1' 33"

PROBLEMS.

1. (a) What was the azimuth of Polaris at its greatest western elongation at Boston when the polar distance of the star was $1^{\circ} 14' 12''$? The latitude of Boston is $42^{\circ} 21' N$.

(b) In making an observation for meridian two stakes were set 329 feet apart, marking the direction of the star at elongation. Compute the length of the perpendicular offset to be laid off at one end of the line to obtain the true meridian.

2. What is the approximate Eastern Standard Time of the eastern elongation of Polaris on August 10th at a place in longitude $72^{\circ} 56'$ West?

3. Observation on May 15, 1906, for determining the azimuth of a line from an altitude of the sun. Reading of vernier A of the horizontal circle while pointing on the azimuth mark = $0^{\circ} 00'$. At first pointing on sun, lower and right limbs, vernier A, horizontal circle read $168^{\circ} 59'$; vertical arc read $43^{\circ} 36'$; the Eastern Standard Time was 2h 52m 45s P.M. At second pointing on the sun, upper and left limbs, vernier A, read $168^{\circ} 52'$; vertical arc, $42^{\circ} 33'$; time, 2h 55m 37s P.M. The second pointing on the mark = $0^{\circ} 00'$, the mark being to the left of the sun. The sun's declination at Greenwich Mean Noon was $+ 18^{\circ} 42' 43''.6$ (North). The change for 1 hour was $+ 35''.94$ (sun going north). The latitude of the place was $42^{\circ} 17' N$.; The longitude was $71^{\circ} 05' W$. Find the azimuth of the mark.

4. Observation for latitude. The observed altitude of Polaris at upper culmination was $43^{\circ} 27'$. The polar distance of the star was $1^{\circ} 12'$. What was the latitude of the place?

5. Observation for latitude. The observed maximum altitude of the sun's lower limb on August 10th, 1906, was $66^{\circ} 29'$. The Eastern Standard Time was approximately 11h 50m A.M. The semi-diameter of the sun was $15' 48''.7$. The declination of the sun at Greenwich Mean Noon was North $15^{\circ} 46' 13''.3$ (+). The difference for 1 hour was $- 43''.46$ (sun going south). What was the latitude of the place?

CHAPTER VIII.

LEVELING.

218. DEFINITIONS. — Leveling consists in ascertaining differences in elevation; there are two kinds, *Direct Leveling*, and *Trigonometric Leveling*. The former alone will be considered in this book, as trigonometric leveling is used only in advanced surveying work.

Wherever extensive leveling operations are to be carried on it is necessary to have a system of reference points called *bench marks* (*B.M.s.*), the relative heights of which are accurately known. These heights are usually referred to some definite zero plane, such, for instance, as *mean sea-level* or *mean low water*, and the height of a point above this plane is called its *elevation*. This plane is called the *datum*. (See Art. 237, p. 211, and Art. 250, p. 226.) Strictly speaking it is not a plane but a level surface, i.e., it is at every point perpendicular to the direction of gravity. If mean sea-level is not known a datum can be arbitrarily assumed.

219. LEVELING TO ESTABLISH BENCH MARKS. — When it is necessary to run a line of levels to establish new bench marks the rod is first held on some bench mark the elevation of which is accurately known, and a backsight taken (Art. 116, p. 85). If this backsight is added to the known elevation of the bench mark it gives the *height of the instrument* (*H. I.*) above the datum. A *turning point* is then selected ahead on the route (to be traversed), and a foresight taken on it. (See Art. 224, p. 202.) If the foresight is subtracted from the height of the instrument the elevation of the turning point is obtained. When a target rod is used it is customary to take readings on bench marks and turning points to thousandths of a foot, and in this case often more than one rod-reading is taken on each point. If the first and second readings agree within 0.002 ft. it is unnecessary to take more readings; if they differ by a greater amount it may be necessary to take three or four or even more readings to properly determine the correct value. The object of taking

more than one reading is not so much to increase the precision as to check the former readings.

When it is desired to establish a bench mark a suitable point is selected and **used as a turning point**. The elevation of this bench mark could be obtained by simply taking a foresight upon it and not using it as a turning point, but by making the bench mark also a turning point it becomes a part of the line of levels and if the levels check, the elevation of the bench mark is also checked. Each bench mark established should be carefully recorded by a description or a sketch, or both. The elevations of the remaining turning points are as accurate as the elevations of the bench marks themselves, so that any of the turning points might be used as a bench mark. Consequently it is advisable to describe those turning points which can be readily identified so that they may be used when it is not convenient or possible to use one of the established bench marks.

In leveling up or down slopes the levelman should be able to judge quickly where to set his instrument in order to have it the desired height above the turning point. In going downhill the rod-reading of the backsight should be as small as possible in order to overcome the height with the minimum number of set-ups of the level. But while the levelman may waste much time by having large backsights necessitating additional set-ups, it is also possible for him to waste quite as much time in attempting to place his instrument so as to get very small backsights. The proper way to handle the instrument is as follows. Set up roughly (without pressing the tripod legs into the ground), turn the telescope toward the rod and then level it, approximately, in that direction. By sighting along the outside of the telescope, the approximate place where the line of sight will strike the rod can be noted and the distance the instrument should be moved up or down the slope can readily be estimated. Then move to the new position, level up carefully, and proceed to take the backsight. This general procedure should be followed whether leveling up or down a slope.

220. In this work it is very important to eliminate as far as possible errors of adjustment in the instrument. If at every set-up of the level the foresight and its corresponding backsight are

taken at points which are equally distant from the instrument such errors will be eliminated. If the level is not in perfect adjustment the resulting error in any reading is proportional to the distance. At equal distances from the instrument the errors are equal, and, since it is the difference of the rod-readings that gives the difference in elevation, the error is eliminated from the final result by this method. By making the length of foresights and backsights equal on turning points it is possible to eliminate not only the error due to non-adjustment of the bubble but also any error due to non-adjustment of the objective tube, since this will occupy the same position in the telescope in each sight. The distance to the backsight is determined by the place where the instrument is set up, and the rodman, as he passes from one turning point to the next, can by pacing make the foresight distance approximately equal to that of the backsight. The line of levels should be "closed" by continuing the leveling until the original bench mark, or some other bench mark whose elevation is well established, is reached.

221. The notes for this work may consist of five columns, as shown in Fig. 86. The height of instrument is obtained by adding the backsight to the elevation of the point on which it is taken. The elevation of any point is found by subtracting the foresight for that point from the height of the instrument. Notice that the

FIG. 86. BENCH MARK LEVEL NOTES.

calculations may be checked by adding the foresights and the backsights. The difference of these sums should be the same as the difference in elevation between the first and last points.

222. Double Rodded Lines. — A good check on the line of levels may be secured by running a double line of turning points. Instead of taking a foresight on a single turning point, foresights may be taken on two different points near together, from the same set-up of the instrument. When the level is set up again a backsight is taken on each turning point and two independent values of the new height of instrument are obtained. In ordinary bench mark leveling these two values should not differ by more than 0.002 or 0.003 ft. from the previous difference, i.e., if the two heights of instrument differed by 0.013 at a certain set-up they should not differ by more than 0.016 nor less than 0.010 at the next set-up. If the two turning points of a pair are so chosen that their difference in elevation is more than a foot then any mistake of a foot in the computations or in reading the rod will be immediately detected.

In this way, by little additional work the accuracy of the levels may be checked as the work progresses. This method of using double turning points is particularly useful in running long lines of levels where no established bench marks are available for checking.

223. A set of notes illustrating double turning points is shown in Fig. 87. It will be noticed that the higher and lower

FIG. 87. BENCH MARK LEVEL NOTES, DOUBLE RODDED LINES.

turning points of a pair are arranged in a systematic order. The readings in this case have been taken on the lower turning point first at each set-up. It is very important that some definite system shall be followed so that the two lines of levels will not be confused.

224. Bench Marks and Turning Points. — Both the bench marks and the turning points should be such that their elevations will not change during the time they are needed. The only difference between the two is that turning points may be of use for only a few minutes while bench marks may be needed for many years. Bench marks should be very carefully and accurately described, and their heights should be checked before being accepted as correct. They are frequently taken on such points as these:— stone bounds, tops of boulders, spikes in trees, and on sills, stone steps, or underpinning of buildings. Curb stones or tops of hydrants are also used but are not so permanent. As it is often impossible in a new country to find existing points where bench marks can be established, it is usual in such cases to set stone monuments or iron rods and to carefully determine their elevation. The U. S. Geological Survey, for example, sets an iron pipe with a cap on the top of it; or in some cases a plate with a horizontal line across it in the masonry wall of a building. Some of the bench marks of the U. S. Coast and Geodetic Survey and of the Missouri River Commission consist of stones buried 3 or 4 ft. under ground. The exact bench is the top of a spherical headed bolt set in the top of the stone. This is reached by lowering the rod through an iron pipe which extends to the surface of the ground.

Bench marks should be established at frequent intervals for convenience in dependent work. Some surveyors consider it advisable to have two bench marks in the same locality to serve as checks on each other. In choosing a bench or a turning point it is best to select a point which is slightly raised so that the rod will always rest on exactly the same point. A rounded surface is better than a sharp point, especially when it is on a rock, as the rod may chip off a small piece and alter the elevation. If a turning point is taken on a flat surface it is difficult to get the rod at exactly the same height each time. Bench

marks are, however, sometimes established on flat level surfaces such as the coping stone of a masonry structure, because permanence is of more importance than great precision. Bench marks are not only described in the notes, but are themselves frequently marked by red chalk, by chisel marks, or drill-holes.

225. LEVELING FOR PROFILE.— Profile leveling is for the purpose of determining the changes in elevation of the surface of the ground along some definite line. The line is first "stationed," i.e., marked at every hundred feet or such other interval as is desired. The level is set up and a backsight taken on a bench mark to determine the height of the instrument. Foresights are then read on as many station points on the line as can be conveniently taken from the position of the instrument. Intermediate sights are taken at any points where marked changes of slope occur, and the plus stations of these intermediate points are recorded with the rod-readings. It will be noticed that here the terms foresight and backsight do not refer to the forward and backward directions. A backsight is a reading taken on a point of known elevation for the purpose of obtaining the height of the instrument. A foresight is a reading taken on a new point to determine its elevation. For this reason backsights are frequently called *plus sights* (+ S), and foresights are called *minus sights* (— S). When it is necessary to move the level to a new position in order to take readings on stations ahead, a turning point is selected and its elevation determined. The level is then taken forward and its new height of instrument determined by taking a backsight on the turning point. This general process is continued until the end of the line is reached.

A line of levels should be checked by connecting with some reliable bench mark if possible. If there are any bench marks along the line of levels they should be used as turning points if convenient, or at least check readings should be taken on them in order to detect mistakes. In such a case it is evident that the reading taken on the bench mark is really a foresight since its elevation is being found anew from the height of instrument. Readings on bench marks and turning points should be taken to thousandths or to hundredths of a foot, depending upon the accuracy desired. If the elevations of the profile are de-

sired to the nearest hundredth of a foot, as in the case of a railroad track, the turning points should be taken to thousandths of a foot. Elevations on the surface of the ground will not usually be needed closer than to tenths in which case the T. Ps. are taken only to hundredths. In calculating the elevations the results should not be carried to more decimal places than the rod-readings themselves, otherwise the results will appear to be more accurate than they really are.

FIG. 88. PROFILE LEVEL NOTES.

226. Profile notes are kept as shown in Fig. 88. In this case also the heights of instrument and the elevations of turning points may be checked by means of the sums of the foresights and backsights, provided only the sights on turning points and the initial and final benches are included. If it seems desirable the elevations of stations may be checked by means of

differences in foresights. The difference between the elevations of any two points, which are obtained at the same set-up of the instrument, is equal to the difference between the foresights taken on these points. For example, if the difference between the foresights on stations 4 and 5 is 3 ft. this should also be the difference between their elevations. In these notes the elevations of B. Ms. and T. Ps. are put in a different column from the surface elevations simply for the sake of clearness, but many surveyors prefer to put all the elevations in the same column. Another arrangement of columns which will be found convenient when plotting the notes is to place the station column immediately to the right of the elevation column.

FIG. 89.

Fig. 89 represents a rough plan and profile of the line of levels shown by the notes in Fig. 88. Angle points in the transit line are shown in the plan, but they do not appear in the profile of the line. It will be noticed that the T. Ps. and B. Ms. are not on the transit line in plan, and that they consequently do not appear on the profile. It is not customary to introduce

any sketches into the profile notes except those used in describing bench marks or turning points.

227. CROSS-SECTIONING. — If it is desired to know the shape of the surface of a piece of ground, the area may be divided into squares and the elevation taken at each corner of these squares and at as many intermediate points as seem necessary to determine the changes of slope. These surface elevations are obtained to tenths of a foot. The squares which may be anywhere from 10 ft. to 100 ft. on a side are laid out with the transit and tape, stakes being driven at the corners. It is well to choose some long line of the traverse as the primary line from which the cross-section system is to be laid out. The points are usually designated by a system of rectangular coördinates, one set of parallel lines being marked by letters and the other by numbers, as shown in Fig. 90. For example, the

point *p* would be called (*C*, 7); the point *s*, (*D*, 5); the point *r*, (*B* + 80, 4 + 35); etc. The notes are kept as in profile leveling except as to designation of points.

228. Use of the Tape Rod in Cross-Section Work. — In this work, where there are a large number of elevations to be calculated, it will save much time to use a tape rod (Art. 106, p. 81), which is so arranged that no elaborate figuring is required. In this rod the numbers increase from the top toward the bottom, the opposite way from ordinary rods. The level is

set up at a convenient point and the rod held on a bench mark. The tape, or band, on the rod is then moved up or down as directed by the levelman until he reads the feet, tenths, and hundredths which are the same as those of the elevation of the bench mark, e.g., if the elevation of the B. M. is 195.62, the tape will be moved until it reads 5.62. If the rod is then held on a point 1.61 ft. lower than the bench, the rod-reading will be 4.01, since with this rod the readings decrease as the rod is lowered. The elevation of the point is then 194.01 ft., or sufficiently precise for topographic work, 194.0 ft. In this way the elevations are read directly on the rod to feet and decimals of feet, the tens and hundreds of feet being supplied mentally. Obviously the only notes kept are the columns of stations and elevations.

229. CROSS-SECTIONING FOR EARTHWORK.—Whenever it is desired to ascertain the quantity of earthwork in an excavation or an embankment, it is necessary to take levels to determine the vertical dimensions, and to obtain the horizontal dimensions by means of the transit and tape. The three general cases where the quantity of earthwork is to be estimated by the engineer are: (1) an excavation or embankment having a known base and side slopes as in the construction of a railroad or a highway, (2) an irregular excavation from a bank of earth called a *borrow-pit*, (3) a trench excavation such as is used for sewer construction.

230. (1) Road Cross-Sections.—Cross-sections for estimating the earthwork in highways or railroads are usually taken at full station points (sometimes oftener) and at right angles to the center line of the road.* By this method is obtained a section of the general shape shown in Figs. 91 and 92. These cross-sections are taken in the field before the construction begins so that a proper record of the surface heights can be obtained before the ground is disturbed.

From the plan of the proposed road its alignment is staked out and a profile is taken along the center line, which is subsequently plotted (Art. 225, p. 203). On this profile the *grade line* is drawn, which corresponds to the finished surface of the road. Roads are usually first finished to *sub-grade*, which is below the

* For a more complete treatment of this subject see "Railroad Curves and Earthwork," by Professor C. F. Allen, published by Spon & Chamberlain, New York.

completed surface by an amount equal to the thickness of the road covering, i.e., the pavement of a highway or the ballast in the case of a railroad. The width of the base of the road and the inclination of the side slopes are known. For ordinary gravel the slope is usually $1\frac{1}{2}$ ft. horizontal to 1 ft. vertical, called "a slope of $1\frac{1}{2}$ to 1."

For construction work the engineer sets grade stakes at every full station or oftener on the center line and at both sides where the finished slope intersects the surface of the ground, e.g., at points *A*, *B* and *C* on Figs. 91 and 92. All of these

FIG. 91. EXCAVATION.

FIG. 92. EMBANKMENT.

stakes are marked, giving the amount of "cut" or "fill" to be made at these points. The cut or fill marked on the stakes at *B* and *C* is the vertical distance from the base of the road to the surface of the ground at these points, e.g., the distance *bc*.

These cuts and fills are determined in the field by the following method. The level is set up and the height of instrument obtained from some convenient bench mark. Then, the elevation of the finished grade being known (from the profile prepared in the office), the difference between the height of instrument and the elevation of the finished road will give what is called the *rod-reading for grade*, i.e., the rod-reading which would be obtained if the foot of the rod could be held on the finished surface of the road. Then the rod is held on the surface of the ground at the center stake and a reading is taken (to the nearest tenth of a foot), and the difference between the rod-reading for grade and the rod-reading on the surface will give the cut or fill at that point, and this is marked on the center grade stake thus, C5.2 or F4.7.

231. SETTING SLOPE STAKES. — The points where the side slopes intersect the surface of the ground are found by trial as follows. Hold the rod at a point where it is estimated that the side slope will cut the surface, and take a rod-reading. The difference between this rod-reading and the rod-reading for

grade will give the cut or fill at this point, from which the distance out from the center of the section to the point on the side slope having this cut can be computed. This distance out equals $(\frac{1}{2} \text{ base} + \text{cut} \times \text{slope})$. Then the distance is measured from the center to the rod, and if the measured distance equals the computed distance the rod was held at the right place and the stake should be driven and marked with the cut or fill at that point (distance bC , Fig. 92). If the measured distance does not agree with the calculated distance a second trial must be made by holding the rod at another point and repeating the operation. The difference between the measured and calculated distances is an aid in judging where the rod should be held at the second trial. After a little practice it will be possible to set the slope stake at the second or third trial.

232. EARTHWORK NOTES FOR ROAD CROSS-SECTIONS. — The notes for this work will contain the cut or fill at the center, the cut or fill at either side, and the corresponding distances out. A cut is usually written in the notes as a plus (+) height and a fill as a minus (—) height; but the stakes

FIG. 93. CROSS-SECTION NOTES FOR A ROAD.

are marked C or F rather than $+$ or $-$. If the surface is irregular levels are taken at intermediate points and are recorded as shown opposite Sta. 11 + 50, and Sta. 12 in the notes, Fig. 93. Where the surface of the ground is parallel to the

base of the road, as in Sta. 10, the section is called a *Level Section*. Where the surface of the ground is not parallel to the base and where three cuts or fills only are recorded, as at Sta. 11, the section is called a *Three Level Section*. If, besides the three readings which are taken for a three level section, two more intermediate readings are taken one directly over each end of the base, as at Sta. 11 + 50, the section is called a *Five Level Section*. If intermediate readings (one or more of them) are taken anywhere except over the ends of the base, as in Sta. 12, the section is called an *Irregular Section*. For methods of computing the amount of earthwork see Chapter XII.

It will be noticed that in the column of the notes headed "Cross-Sections" the distances out appear above and the corresponding cuts below the lines. Besides this set of notes there is a simple set of level notes similar to Fig. 86, p. 200, from which the height of instrument is determined. This is conveniently kept in another part of the note-book, often at the back of the book.

233. (2) Cross-Sections for Borrow-Pits.—The ground is first staked out in squares or rectangles and the elevation at each corner and at every change in slope is determined as explained in Art. 227, p. 206. Then the work of excavating is carried on, and when it is desired to determine the amount that has been excavated, the same system of cross-sections is again run out and the new elevations at the corners and at the necessary intermediate points are determined.

The notes are kept as shown in Fig. 90, p. 206. For methods of computing the earthwork in borrow-pits see Art. 373, p. 342.

234. (3) Cross-Sections for Trench Excavation.—The surface elevations are determined by making a profile of the line. The grade of the bottom of the trench is obtained either from the plan or by direct leveling. The width of the trench is measured wherever it changes and the stations of these places noted. For methods of computing the quantity of earthwork see Chapter XII.

235. LEVELING TO ESTABLISH A GRADE LINE.—The level may be used for setting points at desired elevations as, for example, in establishing the grade line of a sewer. To set any point at a given elevation, set up the level and take a backsight

on a bench mark, thus determining the height of instrument. Subtract the given elevation from the height of instrument and the result is the rod-reading for grade. Raise or lower the rod until the horizontal cross-hair indicates this reading. The foot of the rod is then at grade. This is usually set for construction work to hundredths of a foot; for some purposes tenths of a foot will be sufficiently exact. If a target rod is used the target is set at the proper reading, and the bottom of the rod is at grade when the cross-hair bisects the target.

If the grade line comes beneath the surface of the ground and cannot be reached a point may be set a convenient whole number of feet above grade and the depth marked on a stake, or *vice versa* if the grade line comes far above the surface.

236. "Shooting in" a Grade Line. — To save time and to diminish the liability of mistakes, grades are often set by a method known as "shooting in" the grade. First set a point at the proper elevation at each end of the straight grade line. The instrument (usually a transit with a telescope bubble) is set up 6 or 8 inches to one side of the first point, and the distance from the top of the first stake to the axis of the telescope is measured with the tape or rod.* Then the rod, which is set at this reading, is carried to the last point on the straight grade line, and, while it is held vertical on this point, the instrument man raises or lowers the telescope until the horizontal cross-hair is on the target, clamping the instrument in this position. If a level is used the horizontal cross-hair is set by means of the leveling screws; but if the transit is used the cross-hair is set by means of the clamp and tangent screw of the vertical motion. The line of sight is then along an inclined line parallel to the grade line. All intermediate points on the grade line are then set by raising or lowering the rod until the target coincides with the horizontal cross-hair.

237. TO ESTABLISH A DATUM PLANE BY MEANS OF TIDAL OBSERVATIONS. — Whenever it is necessary to establish a datum from tidal observations it may be determined as follows. Set up

* Where the grade is flat some surveyors prefer to set the instrument just behind the point instead of to one side of it.

a vertical staff, graduated to feet and tenths, in such a manner that the high and low water can be read. Read the positions of high and low water for each day for as long a period as practicable. The mean value obtained from an equal number of high and low water observations will give the approximate value of mean sea-level. If the observations extend over just one lunar month the result will be fairly good, whereas in less than one month a satisfactory result cannot be obtained; to determine this accurately will require observations extending over several years.

The proper location of the gauge is an important factor in obtaining the true mean sea-level. The place chosen for setting up the gauge should be near the open sea, so that local conditions will not influence the tide. It should be somewhat sheltered against bad weather. The water should be deep so that at the lowest tide the water will stand at some height on the gauge.

At the beginning of the series the zero of the staff and some permanent bench marks should be connected by a line of levels. This should be tested occasionally to see if the staff is moved. After the reading of the rod for mean sea-level is found the elevation of the bench mark can be computed.

238. The Staff Gauge. — This is a form of gauge (Fig. 94) which can be easily constructed, and which is sufficient where only a short series of observations is to be made. If made in sections not over 3 feet long, as described below, it can easily be packed in a box for transportation. Each section consists of two strips of wood about $1\frac{1}{2}$ inches square, and 3 feet long, fastened together at the ends by strips of brass, leaving a space between them of about 1 inch. In this space is placed a glass tube of about $\frac{3}{4}$ inch diameter and held in place by brass hooks. On one side of the tube is a red strip blown into the glass. When the gauge is set up for observations the sections are screwed to

FIG. 94. STAFF GAUGE.

a long vertical piece of joist. The ends of the tube are nearly closed by corks, in which small glass tubes of approximately 1 mm. (inside) diameter have been inserted. When the water rises in the main tube, the red strip appears to be much wider than it really is on account of the refraction of light by the water. Above the water surface the strip appears its true width. By observing the position of the wide strip the height of the water surface can be read within a hundredth of a foot. The heights are read on a scale of feet painted on the wooden strips. If the size of the small glass tube is properly chosen, the fluctuations of the water surface outside will not disturb the water in the tube, so that the reading is a fair average of the water surface. A gauge of this sort may be read by means of a transit telescope or field glass at a distance of several hundred feet.

When a long series of observations is to be made a self-registering tide gauge should be used. A description of such a gauge may be found in the Reports of the U. S. Coast and Geodetic Survey.* (See Volume II, Arts. 258-9, p. 288-91.)

239. LEVELING ACROSS A RIVER. — While the effect of curvature and refraction (Art. 118, p. 87) is usually negligible in leveling operations, it may in certain special cases become of great importance to eliminate this error. For example, it is sometimes necessary to carry a line of levels across a river of considerable width, say, half a mile. In this distance the correction for curvature and refraction amounts to about 0.143 ft. under normal conditions, which in a line of bench levels is too large a quantity to neglect. If the correction as derived from formulas could be depended upon under all circumstances it would be sufficient to compute and apply it to the rod-reading. But the amount of the refraction correction is so variable that the actual value often differs considerably from the computed value.

If it is desired to obtain the difference in elevation between two distant points with great accuracy it will be necessary to use a method which will **eliminate** the effects of curvature and refraction no matter what their actual amount may be. In Fig. 95 suppose a backsight were taken on T. P.₁ with the instrument

* Report for 1897, pp. 315-320 and pp. 480-489.

Report for 1853, pp. 94-96.

at A and then a foresight taken on $T. P._2$. The elevation of $T. P._2$ as computed from $T. P._1$ will be too low by the amount ab , since the foresight on $T. P._2$ is too great by this amount. If the difference in elevation is determined by the instrument at B the backsight on $T. P._1$ is too large by the amount cd . Hence the H. I. of the instrument at B is too great, and consequently

FIG. 95. LEVELING ACROSS A RIVER.

the elevation of $T. P._2$ too great by the amount cd . The mean of the two determinations would give the true elevation of $T. P._2$ if $ab = cd$, but this occurs only when the two sights are taken under the same atmospheric conditions. Therefore it will be seen that the two sights must be taken **simultaneously**. In order to eliminate the errors of adjustment* in the instrument it is necessary to use the same instrument at both ends of the line. To accomplish both of these results at once it is necessary to take simultaneous readings with two instruments and then to repeat the operation with the instruments interchanged. The magnifying powers of the two telescopes and the sensitiveness of the two spirit levels should be about equal in order to give the best results. It will be noticed that this process is similar to that of the peg adjustment (Art. 128, p. 91).

* Errors due to non-adjustment are of unusual importance because the sight is much longer than that used in adjusting the instrument.

PROBLEMS.

1. Compute the following set of level notes.

Sta.	+ S.	H. I.	- S.	Elev.
B. M. ₁	4.702	21.129		16.427
B. M. ₂	11.846		6.727	11.402
T. P. ₁	7.276		9.689	11.44
B. M. ₃	8.760		4.726	11.63
T. P. ₂	0.687		11.000	11.29
B. M. ₄	1.607		8.496	5

2. Compute the elevations in the following set of level notes.

Sta.	B. S.	H. I.	F. S.	Elev.
B. M. ₁₂	6.427		4.273	62.473
20			6.2	
21			7.4	
+42			5.2	
22			4.7	
T. P. ₂₇	4.724		9.976	
23			11.2	
+63			10.4	
B. M. ₂₂	0.409		7.482	
24			11.2	

3. Compute the elevations in the following set of level notes.

Sta.	B. S.	H. I.	F. S.	Elev.
B. M. ₂₄	6.214			84.238
T. P. ₁ L.	3.515		9.280	
T. P. ₁ H.	2.152		7.919	
T. P. ₂ L.	2.971		8.263	
B. M. ₂₃ H.	2.338		7.629	
T. P. ₃ L.	4.278		7.529	
T. P. ₃ H.	2.646		5.894	
B. M. ₂₂ L.	5.721		6.072	
T. P. ₄ H.	4.837		5.187	
B. M. ₂₇			5.817	

4. Make up a set of cross-section notes for road construction which shall be consistent with the following data: width of road, 50 ft., slopes $1\frac{1}{2}$ to 1; grade elevation of Sta. 0 = 107.20; grade, + 1.4. Show complete notes from Sta. 0 to Sta. 3 inclusive as follows: Sta. 0, a level section; Sta. 1, a three level section; Sta. 2, a five level section; Sta. 3, an irregular section.

CHAPTER IX.

CITY SURVEYING.

240. INSTRUMENTS USED. — Owing to the comparatively high value of land in cities and to the fact that a large proportion of city surveying is the establishing of lines and grades for construction work, the chain and compass are discarded entirely and the steel tape and transit are used.

241. Tapes and Tape Measurements. — The tape most commonly employed is the light 100-ft. steel tape, graduated to hundredths of a foot, described in Art. 7, p. 5. All ordinary measurements are taken in the usual manner, the pull and the horizontal position of the tape being judged by the men taking the measurements. But frequently it is necessary to obtain results with a greater degree of accuracy than is afforded by the ordinary method of measurement. For example, in measuring the base-line for triangulation work or in the survey of the valuable portions of large cities, there is call for an accuracy of measurements which can only be obtained by using a method which will insure a uniform pull on the tape, a careful alignment, little or no sag in the tape, and some means by which the temperature of the tape can be taken and its correction applied to the results. In such cases the pull is measured by use of a tension handle (ordinary spring balance) which can be attached by a clamp to any part of the tape, the alignment is given with the transit, and, where feasible, just enough pull is given so that the stretch in the tape equals the shortage due to sag. The correction for temperature can be computed from the difference between the temperature of the tape taken in the field and the temperature at which it is standardized (Art. 19, p. 13). The tape should be compared with the *City Standard* (Art. 243, p. 218), at a definite tension, and the temperature noted at the time. From this information all of the field measurements can

be reduced to agree with the City Standard and very accurate results may be obtained.

Where the ground is not level and there is call for frequent plumbing it is impossible to obtain accurate results unless the plumbing is carefully done by experienced tapemen. For very accurate work it may be desirable to entirely eliminate the plumbing. This is sometimes done by measuring directly on the surface (on the slope) from point to point, and by means of the level instrument and rod the relative elevations of these points are obtained and the horizontal projection of the slope distances computed. Instead of measuring the difference in elevation between the two ends of the line, the angle of inclination of the slope line is often measured on the vertical arc of a transit which is set up over one of the end points.

The government Bureau of Standards at Washington will, for a nominal charge, standardize tapes; and city and private engineers frequently avail themselves of this opportunity. This Bureau will give the exact length of the tape at a given temperature or the temperature at which the tape is of standard length, whichever is desired by the engineer. It is well to have the tape also tested at a few intermediate points, e.g., the 25 ft., 50 ft., and 75 ft. marks. One tape which has been standardized should be kept in reserve, with which tapes in service can be compared both when new and after being mended.

Besides the ordinary steel tape, steel or metallic tapes reading to tenths of a foot are used in taking measurements for making approximate estimates of construction and for measuring earthwork, paving, and the like.

242. Transits and Levels. — The transits usually employed in city work read to 30'' or to 20''; and for most city work no finer graduation is necessary. With these instruments the required precision in reading angles on triangulation work can be obtained by repeating the angles as explained in Art. 59, p. 48. In such work, however, it will be of advantage to have an instrument reading to 10''. It is well also to have one or more transits equipped with stadia hairs for use on rough surveys.

Much of the city work, such as the staking out of new streets,

paving, sewers, or curbs, requires the establishment of both lines and grades. Since this class of work does not as a rule call for very precise results, the measurements and rod-readings are usually taken to hundredths of a foot. It is not convenient, for the ordinary surveying party of three men, to carry both a transit and a level instrument in addition to the ordinary equipment of sighting-rods, level-rod, stakes, tape, etc., so the engineer's transit, with a level attached to the telescope, is extensively used in setting grades as well as in establishing lines. For this reason several of the transits in a city office should be equipped with telescope levels and some of them with vertical arcs. The degree of precision possible with an engineer's transit is entirely satisfactory for all ordinary leveling.

Where leveling work alone is to be done the ordinary wye or dumpy level instrument is used together with target or self-reading rods. (See Chapter IV.) For bench leveling it is customary, in large cities at least, to use a *precise level*, an instrument which is similar in principle to the ordinary level but which has a more delicate bubble and a telescope of higher power, and is therefore capable of yielding more accurate results.

243. CITY STANDARD.* — It is customary in all large cities to have a standard of length, usually 100 ft. long, established in some convenient place, often near the office of the City Engineer. It sometimes consists of two brass plugs set in a stone pavement, or it may be a long steel rod supported on rollers on the side of a wall or building in such a way that the rod can expand or contract freely. The end points and the 50-ft. point are so marked that they can be readily found and used by any surveyor who desires to test his tape.

A city standard is often established by carefully transferring the length of some other standard, by means of different tapes and under different weather conditions; or it can be established by means of a tape which has been standardized by the U. S. Bureau of Standards (Art. 241, p. 216). The City Standard is

* See a paper entitled "The 100-foot Standard of Length of the Boston Water Works at Chestnut Hill Reservoir," by Charles W. Sherman, published in the Jour. Assoc. Eng. Soc., Vol. XVIII, No. 4, April, 1897.

generally placed where it will not be exposed to the direct rays of the sun, and with this end in view it is sometimes covered with a wooden box.

When a tape is tested it should be stretched out at full length beside the standard and left there until it acquires the same temperature as the standard before the comparison is made, to avoid the necessity of applying a temperature correction.

CITY LAYOUTS.

244. In laying out or extending a city it is the duty of the surveyor to consider the future needs of its population and to design the general plan of the city accordingly. Nearly all of our large cities show examples of lack of forethought relative to future growth, which have necessitated the outlay of millions of dollars for revision of street lines, sewer systems, water works, and the like.

Occasionally the engineer is called upon to plan a new city or to design the general layout of the suburbs of an existing city. The basis for such work should be a topographic map of the entire area, for the topographic features of a locality will influence its development to a marked degree.

245. STREETS. — In planning the arrangement of the streets for a city such features as a water front, a river or lake, the location of an existing railroad, or the probable location of some projected railroad line will determine to a large degree where the business section of the city will be located. This section should then be so divided as to yield the greatest convenience for business purposes. Other sections will be reserved for residential districts, and their design will be of a different character. Easy access should be provided from the business to the residential districts and to outlying towns or adjacent cities.

The streets must be of the proper width to accommodate the traffic they are to carry, and their alignment and grades must be carefully studied with the topographic map as a guide. Adequate drainage of the streets is, of course, one of the most

important features, for which ample provision must be made in establishing the alignments and grades.

In the business section the traffic will move in certain directions, e.g., to and from important points such as a river, railroad station, or freight yard, and this traffic must be provided for by wide streets with easy grades. In the residential portions, narrower streets and steeper grades are permissible when made necessary by the topography of the district.

246. Location of Streets.—In establishing the location of city streets in hilly districts it is probable that to obtain the essential requisites of easy grades and good drainage the topography will govern the street layout. Whereas in a practically level country, with no steep grades in any direction, the street layout can be such that the most direct communication between different parts of the city is secured.

Fig. 96 shows the location of a rectangular system of streets laid out without reference to the topographic features. The lower portion is on rolling ground where this system may be properly applied; but from a study of the contours it will be seen that in the upper portion this method introduces very steep grades on all of the streets which cross the valley and also leaves a hollow in these streets which is difficult to drain. Fig. 97 shows a layout which will obviate this difficulty to some extent, the diagonal streets being located in the valleys to take the surface drainage of surrounding property. It is obvious that the construction of a sewer through these diagonal streets will be much more economical than through the streets as laid out in Fig. 96, for a sewer must have a continual drop toward its outlet, and cannot be laid uphill and downhill like a water pipe.

With reference to directness of communication between different parts of a city the two general systems which have been used in this country are the rectangular block system and a combination of rectangular blocks with diagonal streets, running in the direction of the greatest traffic.

The rectangular system gives the maximum area for private occupation and is consistent with the general style of rectangular building construction. Where the topography admits of it, this system of streets is advisable. Many of our large cities,

FIG. 96. LAYOUT OF STREETS WITHOUT REGARD TO TOPOGRAPHY.

FIG. 97. LAYOUT OF STREETS WITH REGARD TO TOPOGRAPHY.

like Philadelphia, for example, have been laid out in this manner. The streets frequently run parallel and perpendicular to the shore of a lake or river. More often, however, they are laid out in north and south, and east and west directions. When diagonal streets also are introduced they should connect the points between which the traffic is the heaviest. Indianapolis is planned in this manner, having four broad diagonal avenues running from a central park; but the city of Washington (Fig. 98) is the best example of this system in the United States.

247. Size of Blocks and Lots. — No definite size of blocks and lots can be prescribed which will fit all conditions. Experience has shown that the depth of lot most convenient for both business and residential districts is from 100 to 150 feet. In business districts particularly, it is well to provide an alley from 15 to 25 ft. wide running lengthwise through the block. This makes the width of blocks from 215 to 325 feet, which is about the range in existing cities.

The length of the blocks should be in the direction of greatest travel, and this dimension will therefore depend upon the necessity for cross-streets to accommodate the traffic which moves at right angles to the principal line of traffic. In business districts then the cross-streets should be much more frequent than in residential portions of the same city. The length of blocks therefore varies considerably in different cities and in different parts of the same city; ranging all the way from 400 to 900 feet. In New York the typical blocks are 200×900 ft., and 200×400 ft.; in Boston they vary in width from 125 to 252 ft. and in length from 200 to 700 ft., depending upon the locality.

The frontage of lots is frequently 25 ft. in business and congested residential districts and 50 feet or more in suburban districts, but these dimensions are by no means universal.

248. Width of Streets. — The widest streets should in general be the ones which have the greatest traffic. Important business streets should be from 100 to 150 ft. in width, while streets of secondary importance in business districts may be from 60 to 80 ft. wide. In residential districts the main streets

FIG. 98. MAP OF A PORTION OF THE CITY OF WASHINGTON.

should be 60 to 80 ft. wide, but those of lesser importance are often made 50 ft. These widths, however, are more liberal than have been used in many of our older cities, e.g., such cities as Boston, Baltimore, and New York which are especially afflicted with narrow streets.

The alleys which are run through the middle of city blocks should be made from 15 to 20 ft. wide. If they are made narrower than 15 ft. two teams cannot pass each other unless certain parts of the alley are widened for this purpose. Alleys furnish a convenient place for the location of water pipes and sewers.

The width of sidewalks varies greatly with the locality. In business districts, where there is usually a necessity for ample width, some cities devote two-fifths of the entire width of the street to sidewalks; while in residential districts, the sidewalks are frequently much narrower in proportion to the width of the street. In Boston the general rule is to make each sidewalk one-sixth the width of the street. Sidewalks 8 ft. wide are ample for most residential districts. In some localities walks as narrow as 4 ft. are laid out with a liberal grass-plot between the sidewalk and the roadway, which not only gives a pleasing appearance to the street, but also lessens the width of sidewalk and of roadway to be paved and maintained, thereby decreasing the burden of taxation and leaving room for an increase in width of roading if afterwards needed.

249. STREET GRADES. — In connection with the layout of a new city or suburb the grade of the streets is of quite as much importance as the street alignment. While, in the residential districts of some cities, street grades as steep as 10 and 15 per cent. are not uncommon, still it is considered advisable, if possible without excessive cost, to keep the grades down to about 5 or 6 per cent., especially those which extend for any considerable distance. In business districts, where heavy loads are to be hauled, it is desirable that the grades should not exceed 3.5 or 4 per cent. In any case where one street crosses another the grade should be flattened between curb lines to 3 or 4 per cent. if the grade of either street is greater than this amount.

On account of drainage it is well to build a street with a slight grade rather than level. A grade of 6 inches in 100 feet is a good working minimum for proper drainage, and if the street does not have this gradient the gutters must be made of varying depth so as to properly carry off the water. Other elements which govern the rate of grades are the cost of earthwork and the proper balancing of the excavation and embankment in the construction, the effect on abutting property, and the general appearance of the street.

At points where there is a decided change in grade it is customary to introduce a parabolic vertical curve. (Art. 268, p. 242.)

For the purpose of establishing the grades, profiles are made of each street. Levels taken for the purpose of making a profile should include elevations at the center of the street and along both side lines, and it is often desirable to have a cross-section plan of the entire area of the vicinity where the street is to be located. A description of the street grade is written up for acceptance by the proper municipal authorities. When this description has been formally accepted by an order of the City Government the grade is said to have been "established." Such an order may refer to the profile by title or recorded number, instead of a description of the grade. The profile of each street should contain one or more cross-sections on which is indicated to what part of the cross-section the profile refers, i.e., whether the profile grade is the grade of the center of the street, the curb, or the sidewalk at the property line.

The following is an example of a description of an established street grade:—

"Beginning at Station 146 (Maple St.) at the junction of the center lines of Maple St. and Ocean Ave., at grade * 52.00, the grade line falls 0.50 per 100 for 726 ft. to grade 48.37—thence rises 0.82 per 100 for 322 ft. to grade 51.01—thence

* The word *grade* is frequently used to mean the *elevation* of a point. In such a case care should be taken not to confuse the meaning of *grade* with *rate of grade*. The latter is sometimes called *gradient*, a word which has some advantages but is not entirely satisfactory.

falls 0.50 per 100 for 122 ft. to grade 50.40 — thence falls by a vertical curve for 100 ft. as follows :

Sta.	Elev.
157 + 60.....	50.40
157 + 85.....	49.90
158 + 10.....	49.30
158 + 35.....	48.55
158 + 60.....	47.70

thence falls 3.60 per 100 for 239 ft. to Station 160 + 99 (Maple St.), grade 39.10."

250. THE DATUM PLANE. — One of the first tasks of the surveyor in laying out a town site is to establish a datum plane to which all elevations may be referred. It is customary to choose a datum that bears an intimate relation to the topography of the locality. For example, if the town is located on the seashore a series of tidal observations may be taken to determine the mean sea-level or mean low water either of which is often used as a datum (Art. 237, p. 211). The mean level of lakes is used as a datum for many inland cities. Frequently the elevation of some point not far from the town site has been established by the U. S. Geological Survey, the U. S. Coast and Geodetic Survey, or by the line of levels of a railroad ; and by careful leveling the elevation of some permanent point in the town site can be established which will serve as the starting point for all the elevations in the town. Where nothing of this sort is available, the elevation of some point is found by barometer so that the recorded elevation may approximate the actual height above sea-level.

251. ESTABLISHING BENCH MARKS. — When the datum has been determined, bench marks are established by the method explained in Art. 219, p. 198. The establishment, at the start, of a reliable system of bench marks is of utmost importance, in order that the elevations of all parts of the city shall refer to the same datum. In laying out construction work it is absolutely necessary that bench marks which can be relied upon shall be available and sufficiently numerous to be of use in any section of the city without requiring several set-ups of the level to connect a bench mark with the level work that is to be done.

Another advantage in having them close together is that they may serve as ready checks on each other as well as on the work at hand. It is not uncommon for a bench mark to be disturbed, and, if the level work is not occasionally checked on some other bench mark, an error will surely enter into all of the level work which was started from that bench.

252. WATER AND SEWER SYSTEMS. — The water and sewer systems of any community are of vital importance and provision for them must be made in the layout of every town site. The location of the water supply and the storage and distributing reservoirs is a matter of such magnitude that it cannot be discussed in this short treatise.* The conditions essential to an economical water or sewer system will sometimes radically affect the alignment and grades of many of the streets. The gradients of water pipes are of little importance since the water is working under pressure, and the pipes can be laid uphill and downhill so long as there is sufficient "head" to force the water through the pipes.

In a sewer system the problem is far different ; every sewer must have proper gradients, and the entire system must fall gradually from the most remote points to the main sewer outlet. The topographic map therefore is of utmost importance as a basis for a study of this problem.†

STAKING OUT CITY WORK.

Eni. **253. STAKING OUT A NEW DISTRICT.** — In staking out a new district the information at hand is usually a plan of the proposed layout of the streets which has been studied out in the office from a map of the district. If this layout has been approved by the municipal authorities the street lines as they appear on the plan are the "established lines."

It is the surveyor's duty to stake out these lines on the ground, connecting them properly with the street lines of the

* See Public Water Supplies by Tourneure and Russell, published by John Wiley & Sons, New York.

† See Sewerage, by Professor A. P. Folwell, published by John Wiley & Sons, New York.

older portion of the city, and in short, to produce on the ground a layout exactly like that on the plan. Sometimes the angles and distances necessary for the layout have been computed in the office, but more frequently these are not determined until the lines are laid out on the ground. In reproducing these lines on the ground the surveyor will often find that the exact dimensions given on the plan do not correspond with his fieldwork owing probably to the fact that his tape differs in length from that used by the surveyor who made the original plan. In such a case he must distribute the discrepancies (unless they are large enough to indicate that a mistake has been made) in the proper manner in his work.

Not infrequently the entire work is staked out from a plan which has been made in the office, and the exact angles and distances as determined in the field are recorded on this plan which then goes to the proper authorities to be put in the form of a city order. As soon as the plan is accepted the street lines should be marked by monuments (Art. 254), so that there may be no difficulty in retracing the lines as they were originally laid out and accepted. If considerable grading work is to be done in building the new streets it may not be practicable to set many of the corner bounds at first on account of the likelihood of their being disturbed. In such cases it is the duty of the surveyor to properly reference the points by cross transit lines or otherwise before construction work begins; for it is important that the layout, as recorded in the city order, shall be accurately and definitely defined so that when the streets are brought to the proper grade and the monuments are finally set they will mark the exact position of the original layout.

254. MONUMENTS. — It is important and at the same time customary to define street lines by setting stone bounds, often called *monuments*, at the street corners and at angles in the street lines. The bounds are set sometimes on the side lines, sometimes on the center lines, and sometimes in the sidewalks.

At street intersections, one monument at the intersection of the center lines will suffice to mark both street lines, but since this point will come in the center of the road pavement where it is likely to be disturbed by traffic or by street repairing it is sel-

dom placed there. The more practicable method is to define the street lines by marking the side lines at the angles or, in the case of rounded corners, at the beginning and end of the curves. It is not necessary that all four corners of a street intersection shall be marked, as a bound on one corner will define the side lines of the two streets and, the width of the streets being known, the other sides can easily be determined. Nor is it necessary to place a bound at one of the corners of every street intersection, provided a street is straight for several blocks, although it is good practice to do so. On account of the liability of bounds which are placed on the side lines of the street being disturbed by building operations, some surveyors prefer to place them on an offset line, say 2 ft. from the street line. All monuments should be placed with extreme care as regards both their accuracy of position and their stability. If any bounds are set with more care than others, they should be the ones which occur at angle points in the street lines rather than the intermediate bounds which are set along a straight line.

Monuments are usually roughly squared stone posts about 4 to 8 inches square and 3 to 4 feet long, the length depending upon the severity of the climate, e.g., in New England a monument less than 4 ft. long is likely to be disturbed by frost action. They are carefully squared on top and a drill-hole in this end marks the exact point. This drill-hole may be made before the stone is set in place, or after it has been placed so that its center is about in position the exact point may be defined by drilling a hole in the top of the bound. Frequently the hole is filled with lead and a copper nail set in the lead is used to mark the exact point. For nice definition of the point, a copper bolt is inserted and two lines scratched across it; the intersection marks the exact point. When the stone bound is placed at the intersection of the side lines of the streets it is sometimes located entirely in the sidewalk in such a way that its inside corner is exactly on the intersection of the street lines. In such a case the three other corners of the bound are usually chipped off so that there may be no mistake as to which corner defines the line, but the line corner frequently becomes worn off and this practice is therefore not recommended. Some surveyors

use, in the place of stone bounds, a piece of iron pipe or iron plug with a punch-hole in the top of it, driven into the ground or embedded in cement concrete. Long heavy stakes are employed to temporarily define intermediate points or points of secondary importance.

255. Setting Stone Bounds.—When the street lines are laid out the corners are marked by tacks in the top of ordinary wooden stakes. The monuments which are to take the place of the stakes should be set before the frost has entered the ground or before any other disturbance of the stakes has taken place. When the bound is ready to be set the first thing to do is to drive four temporary stakes around the corner stake about two feet from it and in such a way that a line stretched from two opposite stakes will pass over the tack in the head of the corner stake (Fig. 99). Then tacks are carefully set in the tops of

FIG. 99. SETTING A STONE BOUND.

these temporary stakes in such positions that a stretching line running from the tack on one stake to the tack on the opposite stake will pass exactly over the tack in the corner stake.

Then the corner stake is removed and the hole dug for the stone bound. Care should be taken not to dig the hole any deeper than is necessary so that the bound may be set on firm

earth. As to the position of the top of the bound with reference to the surrounding ground, surveyors disagree. Some prefer that the monument should stick out of the ground so that it can be readily found; while others claim that if it projects above the surface the bound is likely to become misplaced by traffic, and therefore that it is better to set it just flush with the ground or slightly below the natural surface. If any grading is to be done in the vicinity the bound should be set so that it will conform to the proposed grade. When the hole for the

bound has been dug to the proper depth it is well to stretch the strings across between the temporary stakes and plumb down roughly into the hole to determine where the center of the bound will come, so that when the monument is dropped into the hole it can be placed so that it will set plumb.

The bound having been set in the hole, the next operation is to fill around it. This should be done with considerable care, the material being properly rammed as the filling proceeds and the bound kept in such a position that the drill-hole in the top of it, if there is one, shall be **exactly** under the intersection of the strings. It is sometimes desirable to put in a foundation of concrete and to fill with concrete around the monument to within a foot of the surface, as shown in Fig. 100, where a very substantial bound is required, or where the ground is so soft as to furnish an insecure foundation. If the top of the bound is plain and the hole is to be drilled after the bound is in place, care should be taken to place the monument so that this hole will come practically in the center of the top in order that it may present a workman-like appearance. After the bound is set exactly in place the temporary stakes are removed.

FIG. 100. STONE BOUND WITH CONCRETE FOUNDATION.

Some surveyors prefer to use only two opposite stakes and one stretching line, the position of the monument being determined by a measurement along the stretching line from one or both of the temporary stakes. Still another method of temporarily tying in the stone bound, and one which many surveyors use, is to set two stakes such as A and B in Fig. 99, and either measure the distance from them to the bound or set them at some even distance from the bound. This process of using temporary stakes and the stretching line is employed also in setting other types of bounds such as gas pipes or iron rods.

In the construction of buildings or fences, monuments are frequently disturbed and too often they are reset by the owner of the property without the services of a surveyor. In rerunning a street line, therefore, a surveyor should be on the lookout for such conditions, and he should be cautious in the use of any monument which he has any reason to suspect may have been misplaced.

256. CURVED LAYOUTS. — It is not unusual for streets to be laid out with curved lines. In the design of boulevards, parks, and residential sections a landscape architect is often called in and the plan he presents is sometimes almost devoid of any straight street lines. (See Fig. 101.) The surveyor must

FIG. 101. CURVED LAYOUT FOR RESIDENTIAL PART OF A CITY.

take this plan and from the design there given stake out the layout and obtain the necessary dimensions to definitely locate all parts of it.

As a rule the landscape architect simply draws on the topographic map his scheme of layout with very few dimensions and leaves the rest to be worked out by the surveyor. Occasionally

the radii of the curves are noted on the plan, but the street widths are often the only dimensions given. If the radii are not given the surveyor must determine from the plan either these radii or some other distances, such as the tangent lengths, so that he can go into the field, and, beginning with some known street line, run out the new street lines in such a way that when the data he determines are plotted the lines will coincide with those on the plan prepared by the landscape architect. As a rule these curved lines can be made up of a combination of circular curves.

257. ELEMENTS OF A CIRCULAR CURVE.— Before considering how to stake out a curve it will be well first to refer to the elements of a simple circular curve. In Fig. 102 which represents a simple circular curve

$OB =$	Radius	$= R$
$AHB =$	Length of Arc	$= L_c$
$AB =$	Long Chord	$= C$
$VA = VB =$	Tangent Distance	$= T$
$VH =$	External Distance	$= E$
$HF =$	Middle Ordinate	$= M$
$I =$	Intersection Angle, or Central Angle	
$V =$	Vertex	
$P.C. =$	Point of Curvature	
$P.T. =$	Point of Tangency	

FIG. 102. CIRCULAR CURVE.

From simple geometric and trigonometric relations,

$$\begin{array}{ll} \text{Tan } \frac{I}{2} = \frac{T}{R}, & T = R \tan \frac{I}{2} \\ \text{Exsec } \frac{I}{2} = \frac{E}{R}, & E = R \operatorname{exsec} \frac{I}{2} \\ \text{Vers } \frac{I}{2} = \frac{M}{R}, & M = R \operatorname{vers} \frac{I}{2} \\ \text{Sin } \frac{I}{2} = \frac{C}{2R}, & C = 2R \sin \frac{I}{2} \end{array}$$

$L_c = R \times \text{Circular measure of } I.$

* The curves used in railroad engineering are usually very flat, so that there is little difference between the chords and their corresponding arcs. This fact

258. STAKING OUT CIRCULAR CURVES. — In Fig. 102 the two lines BC and EA are produced in the field and a point is set at their intersection V , as described in Art. 200, p. 175. The

FIG. 102. CIRCULAR CURVE.

instrument is then set up at V and the central angle I carefully measured, or if point V is inaccessible other angles such as VEC and VCE may be measured from which I can be easily computed.

Then the radius R which is determined from the plan being known, the tangent distance T is obtained by the formula, $T = R \tan \frac{1}{2} I$. Points $P.T.$ and $P.C.$ are then set

and the curve is usually laid out by the method of *deflection angles* as explained in the following article.

259. DEFLECTION ANGLES. — A deflection angle is usually referred to as an angle between a tangent and a chord, e.g., in Fig. 103 angles VAb , VAc , etc., are deflection angles. Since

FIG. 103. DEFLECTION ANGLES.

makes it possible to compute the *length of curve* by a simple approximate method, which, however, is sufficiently exact for most railroad work.

The *Degree of Curve*, which is the angle at the center subtended by a chord of 100 ft., is an element of the circular curve which is used extensively in railroad en-

the angle between a tangent and a chord is measured by half the included arc these deflection angles must be equal to half the angle at the center subtended by the same chord or arc.

If the total length of the curve is divided into an even number of parts, n , the angle at the center under each of these arcs will be $\frac{I}{n}$, and the deflection angle for one chord will be $\frac{I}{2n}$, which in Fig. 103 is the angle VAb . Angle bAc = angle VAb , both being measured by one-half of equal arcs. It follows then that the deflection angle to point

$$\begin{aligned} c &= 2 \times \frac{I}{2n} = \frac{I}{n} \\ d &= 3 \times \frac{I}{2n} = \frac{3I}{2n} \\ e &= 4 \times \frac{I}{2n} = \frac{2I}{n} \\ &\text{etc.} \end{aligned}$$

Evidently, after the first deflection VAb is found, the other deflections can be obtained by simply adding the increment $\frac{I}{2n}$ to the preceding deflection angle, and this is the method which should be used. The deflection angle from the $P. C.$ to the $P. T.$ should be equal to $\frac{I}{2}$, and this check should always be applied to the computations before they are used in laying out the curve.

The chords Ab , bc , cd , etc. are equal since their arcs are equal. With the radius and the central angle $\left(\frac{I}{n} \text{ for one chord}\right)$ given, the chord length can readily be found from the formula,

gineering. The central angle divided by the degree of curve will give the number of 100-ft. chords in the length of the curve, i.e., $\frac{I}{D} = L$ (in 100-ft. stations).

Therefore L (in feet) = $\frac{100I}{D}$. For a complete discussion of railroad curves see "Railroad Curves and Earthwork," by Professor C. F. Allen, published by Spon & Chamberlain, New York.

$c = 2 \sin \frac{I}{2n}$. Since the angle at the center is usually small and the radius large the angle will have to be carried out in some instances much closer than to the nearest minute in order that the length of the chord may be obtained to hundredths of a foot (Art. 371, p. 341). An approximate value for the chord length corresponding to a given arc may be obtained by the approximate formula,

$$l_c - c = \frac{c^2}{24R^2}, \text{ or } = \frac{l_c^2}{24R^2} *$$

in which l_c is the length of the arc, c is the chord length, and R the radius.

The fieldbooks in use by most surveyors contain tables of chords and corresponding arcs for curves of different radii, which assist greatly in shortening these computations.

When the deflection angles have been computed and checked and the chord length found, the instrument is set up at A , (Fig. 103) a foresight taken on the vertex with the vernier reading 0° , and the point b set by measuring Ab and placing b on line by means of the transit on which the first deflection angle VAb has been laid off. Point c is set by measuring bc and placing c on line with the transit on which the second deflection angle has been laid off, and so on, until the last point ($P.T.$) has been set.

It is evident that with the transit at the $P.C.$ the curve could have been laid out just as well by taking the measurements from the $P.T.$ end, and some surveyors prefer to do it this way. Similarly the instrument might just as well have been set up at the $P.T.$ instead of the $P.C.$ and the measurements started from the $P.C.$ if it were found to be more convenient.

* The following will give some idea of the accuracy of this formula.

With $R = 100$ and $c = 25$, the formula gives $l_c = 25.065$, (correct value is 25.066).

With $R = 100$ and $c = 50$, the formula gives $l_c = 50.521$, (correct value is 50.536).

With $R = 1000$ and $c = 100$, the formula gives $l_c = 100.042$, (correct value is 100.042).

This formula will be found very useful if a slide rule is employed for the computation.

It is sometimes necessary to set **definite station points** on the curve rather than to cut the curve up into several **equal** parts as suggested above. The principle is exactly the same as described above; but in figuring the deflection angles and the chord lengths to be used the computations are not quite so simple. No trouble will be experienced, however, if it is borne in mind that **the total deflection angle to any point is equal to half the central angle to that point from the P.C.**, and that **the central angle for any arc bears the same relation to the entire central angle that the arc does to the entire length of curve.**

260. Keeping the Notes.—In a curved street the notes of alignment generally refer to the center line, the two side lines being parallel to the center line. All three of these lines have to be run out by the use of chords and deflection angles; Fig. 104 is an example of a concise form of notes for this work. In

Description of curve	Station	Distance (Arc)	Chords			Deflection Angles	Remark
			Left	Center	Right		
			Width of Street 70 Feet.

L _c =180.08	16+72.42						P.C.

FIG. 104. NOTES OF A CIRCULAR CURVE.

the first column is a description of the curve, which refers to the center line of the street. This particular curve is marked "To Right" meaning that it deflects to the right while passing around it in the direction in which the stations run. In the third column are the distances measured on the actual arc along the center line. The next three columns headed "Chords" are the chord measurements across the curve from station to station on the left side line, the center line, and the right side line of the street, the terms left and right meaning left and right looking in the direction in which the stations run. In the column headed "Deflection Angles" are the total deflections to be laid off with the instrument set up at the P.C. These same deflection

curve from d to B just as though it were an independent curve beginning at d and ending at B .

263. SECOND METHOD.—When the transit has been set up at d , the vernier is set at 0° and a backsight taken on A . Then an angle equal to the deflection angle VAd is laid off on the arc; this will cause the telescope to point in some such direction as dh . The line of sight is reversed and point e set on hd produced, making the chord de of the proper length. Then point B is set by laying off on the vernier an angle equal to VAB and measuring the chord eB . This method is correct for

$$\begin{aligned} VAe &= VAd + dAe \\ &= fdA + hdf, \text{ being measured by half of equal arcs.} \end{aligned}$$

This second method is sometimes to be preferred since the original deflection angles figured can be used throughout the curve. The first method calls for the calculation of a few more angles; but this is so simple a process that there is probably little choice between the two methods.

264. CURVED STREET CORNERS.—It is the practice in many cities to curve the corners of the streets by introducing a circular curve of short radius. Where both street lines are straight the problem is handled as explained in Art. 258, p. 234.

FIG. 106.

265. * One Street Line Straight, the Other Curved.—In Fig. 106 the curved street line DEF intersects the straight street line AV and at this point the circular curve whose center is C' and with a given radius r is to be introduced to round off the corner. It is required to stake out the curve GE on the ground. In

* The authors are indebted to I. T. Farnham, City Engineer of Newton, Mass., for the solution of the problems given in Arts. 265-6.

angle $CC'E$, $CE = R + r$, $C'E = R' - r$, and CC' being known, compute the angle $C'CE$, $CC'E$ and $C'EC$, which is the supplement of the central angle of the curve $B'B$. Angle $DCB = DCV + VCC' - C'CE$, from which arc DB can be com-

FIG. 107.

puted. Similarly angle $D'C'B' = D'C'V + VC'C - CC'E$, from which arc $D'B'$ is computed. These locate the $P.C.$ and $P.T.$ of the small curve whose center is E .

267. STAKING OUT STREET GRADES. — The fieldwork necessary in setting grade stakes is explained in Arts. 235–6, p. 210. When new streets are constructed the excavation or embankment is first brought to sub-grade, i.e., to the grade of the bottom of the road covering or pavement. The grade stakes set for this work are usually the center and the two side slope stakes, properly marked with the cut or fill, as described in Arts. 230–2, pp. 207–10.

As the work progresses the center stake is dug out or covered up and when the construction has progressed nearly to the sub-

but $NB = 4VH$ (from above)
 therefore $KV = 2HV$,
 or point H is midway between V and K .

The elevation of V is determined from the established grade. The number of 25-ft. stations will determine the distance VA and VB . The elevation of A and of B can be readily computed along their respective straight grade lines.

$$\text{Elev. } K = \frac{\text{Elev. } A + \text{Elev. } B}{2}$$

$$\text{Elev. } H = \frac{\text{Elev. } V + \text{Elev. } K}{2}$$

$$VH = \text{Elev. } H - \text{Elev. } V.$$

Elevations of all the other intermediate points along the curve can be computed by finding the elevation of the points D' , C' , E' , F' , G' , and J' and by adding to these elevations the ordinates $D'D$, $C'CE'$, etc.

$$D'D = J'J = \frac{VH}{16}$$

$$C'C = G'G = \frac{VH}{4}$$

$$E'E = F'F = \frac{9VH}{16}$$

269. CROSS-SECTION OF STREET. — On account of the necessity for draining the surface of a road the center is raised or "crowned" above the grade of the gutters by an amount depending on various conditions. The shape of the road surface is sometimes two planes, running straight from the gutter to a summit or ridge in the center of the street, this ridge being rounded off by rolling; but more frequently it is a curved surface in the form of a parabola or a circle. The ordinary width and crown of streets are such that the parabola and the circle are practically coincident.

When a street is to be paved the curbstones are first set to proper line and grade, then stakes are set for the finished grade of the roadway. The center grade stake is frequently the only

grade given and a templet, or form, which can be set on the curbs and on this center stake is used to give the form of the cross-section. The form of the templet for this work is laid out by the surveyor. If no templet is used he should put in intermediate grade stakes between the center and the curb lines. In either case the surveyor must compute the necessary ordinates to give the proper shape to the surface.

Usually the mean transverse slope of the pavement is given either in the form of a ratio thus :

$$\text{Mean Transverse Slope} = \frac{\text{Crown}}{\text{Half the Width of Carriageway}} = \frac{1}{30}$$

or, Mean Transverse Slope = $\frac{2}{5}$ " per ft.

270. Gutters at Same Elevation. — Fig. 109 represents the

FIG. 109. CROSS-SECTION OF PAVEMENT; GUTTERS AT SAME ELEVATION

cross-section of a pavement and sidewalks. The crown AB is computed from the mean transverse slope and the width of the pavement.

The ordinate DD' at any other point on the parabola $= C'C \times \frac{l^2}{\left(\frac{W}{2}\right)^2}$ since in a parabola the offsets from a tangent

vary as the square of the distance out along the tangent (Art. 268, p. 242). But $C'C = AB$; hence, if D' is half-way from the center to the curb, $DD' = \frac{AB}{4}$.

271. One Gutter Higher than the Other. — When one gutter is higher than the other the following application of the parabola

can be used. In Fig. 110 the maximum ordinate x is at a dis-

FIG. 110. CROSS-SECTION OF PAVEMENT: ONE GUTTER HIGHER THAN THE OTHER.

tance a from the lower gutter. The first step is to find this distance a and then x is readily found from the mean transverse slope since $\frac{x}{a}$ = Mean transverse slope. When x is found the other offsets can be computed as explained in the previous article.

$$\begin{aligned}\text{At } A \text{ the offset} &= \frac{x}{4} \\ \text{at } B &= x - b \\ \text{at } C &= \frac{x - b}{4}\end{aligned}$$

The width of pavement, the difference in elevation of the gutters, and the mean transverse slope being given, the formula for a is derived as follows.

In Fig. 110, W = width of pavement.

R = radius of the circular curve $DACB$.

a = distance from the line of the lower gutter to the highest point of the pavement.

l = distance from the line of the highest gutter to the highest point of the pavement.

b = difference in elevation between the two gutters.

s = mean transverse slope, expressed as a ratio of crown to half the width of pavement.

x = difference in elevation between the lower gutter and the highest point on the pavement.

$$x = \frac{a^2}{2R} \quad (1) \quad (\text{See (1) in foot-note, p. 339.})$$

$$\text{and } x - b = \frac{l^2}{2R} \quad (2) \quad (\text{See (1) in foot-note, p. 339.})$$

$$\therefore x = b + \frac{l^2}{2R}$$

Combining (1) and (2), $a^2 - l^2 = 2Rb$

$$(a + l)(a - l) = 2Rb$$

$$a - l = \frac{2Rb}{a + l}$$

But

$$a + l = W$$

$$\therefore a - l = \frac{2Rb}{W}$$

$$(a + l) + (a - l) = W + \frac{2Rb}{W}$$

$$2a = W + \frac{2Rb}{W}$$

$$a = \frac{W}{2} + \frac{Rb}{W} \dots \dots \dots (3)$$

From (1),

$$2R = \frac{a^2}{x}$$

But

$$\frac{x}{a} = \text{Mean transverse slope} = s$$

$$x = as$$

$$\therefore 2R = \frac{a^2}{as} = \frac{a}{s}$$

$$R = \frac{a}{2s}$$

From (3),

$$a = \frac{W}{2} + \frac{ab}{2s}$$

$$a \left(1 - \frac{b}{2Ws} \right) = \frac{W}{2}$$

$$a = \frac{\frac{W}{2}}{1 - \frac{b}{2Ws}}$$

272. If, instead of assuming the mean transverse slope of the pavement, the elevation of the center of the pavement D (Fig. 111) with respect to the elevation of A and B is assumed,

FIG. 111.

then DC is readily found and the elevation of such points as E or F , which are midway between D and the gutters, are computed from the method explained in Art. 270, eE and fF both being equal to $\frac{DC}{4}$.

Similarly, Elevation $E = \text{Elevation } G + \frac{3DC}{4}$

Elevation $F = \text{Elevation } H + \frac{3DC}{4}$

Elevation $J = \text{Elevation } K + \frac{7DC}{16}$

Elevation $L = \text{Elevation } M + \frac{7DC}{16}$ etc.

273. IRREGULAR SHAPED BLOCKS.—There is a wide variance of practice in the method of cutting up irregular shaped blocks into lots. One good general rule in such cases is to give

FIG. 112. ARRANGEMENT OF LOTS IN A WEDGE-SHAPED BLOCK.

each lot as much street front as is possible consistent with making the side lines of the lots at right angles to the street lines. If the side lines do not run at right angles to the street there will be portions of the lot which are not available for the customary rectangular style of building construction and which are therefore not so desirable for business purposes. This is not of

so much importance in residential districts where the rectangular system is often purposely avoided to some extent, to obtain a layout which has an attractive appearance, as illustrated by Fig. 101, p. 232.

Fig. 112 is an example of an irregular shaped block in which rectangular lots have been planned, the wedge-shaped remnants being thrown into the corner lots.

274. STAKING OUT CITY LOTS.—In staking out the lots of a rectangular block, the corners of which have been established, the most direct method is as follows. The transit is set up on the S. B. at *A*, (Fig. 113), a sight is taken on *B*, and the front

FIG. 113. RECTANGULAR CITY BLOCK.

corner stakes of lots 1, 2, 3, 4, etc., are set, with a tack, exactly on line, in the top of each stake. All such work should be done to the nearest 0.01 ft. It will be well first to measure the line *AB*, to see that it is just 600 ft. long. Since it is assumed that considerable care was used in setting the S. Bs. exactly in the correct position, if it is to be found to be a few hundredths over or under 600 ft., it is probable that this discrepancy is due to the difference between the length of the tape on the present work and that used in the original layout. In such a case the twelve lots must be laid out with equal frontages. For example,

it may be a hot day when the lots are to be staked out and the tape may give a distance from *A* to *B* of 599.88 ft. In this case each lot should measure 49.99 ft. wide.

With the instrument still at *A* and sighted on *C*, point *D* is set by measuring 66 ft. from *C*, and then point *E* is placed midway between *A* and *D*. Whatever slight discrepancy there may be in the distance between the S. B. at *A* and that at *C* is thrown into the depth of the lots rather than the width of the street.

By setting up the instrument at *B* and sighting on *H*, points *F* and *G* are set. Then by setting up at *F* and sighting on *D* the front corners of lots 13, 14, 15, etc., are determined. Another set-up of the transit at *G* with the line of sight on *E* will allow the "back bone" to be run out and the back corners of all the lots established. The check on the lines *AB*, *EG*, and *DF* is their total length. The depth of the lots can easily be checked by taking direct measurements from the front to their rear corner stakes. If a further check is desired the transit can be set up at each of the front corner stakes of the lots on one street and a right angle turned off to check the position of the rear corner stakes and the front corner stakes of the lots on the street beyond.

By the method suggested above the street lines are made straight and the slight inaccuracies which may occur in the field-work are put into the back and side lines of the lots.

Some surveyors prefer, after the front stakes on both streets are located, to set up the instrument at each front corner and locate the back corner stakes by turning a 90° angle and laying out the depth of the lot, at the same time checking the position of the front stakes on the street on the other side of the block. Then the distances along *EG* are measured to check this field-work.

275. STAKING OUT CURB* LINES AND GRADES.—If the line stakes which are set for the curbstones are placed directly on the line of the curb they will be disturbed when the trench is excavated. For this reason they are usually set in the sidewalk on an offset line, say, 3 ft. from the outside edge of the

* Called edgestones in some localities.

curb, and at intervals of about 25 ft. The grade stakes are set at about the same interval, with their tops at grade or at some even distance (6 inches or 1 foot) above or below the grade of the curb. Sometimes the grade stakes are not driven so that their tops bear any relation to the finished grade, but a horizontal chalkmark is made on the side of the stake marking the proper grade. A stake can be marked much more quickly than the top can be driven to the exact grade.

When new curbstones are being set in an old street, stakes cannot as a rule be used. The sidewalks are too hard to permit the driving of stakes, and even if they could be driven those projecting above the surface of the sidewalk would be a source of danger to pedestrians. In such cases it is customary to use heavy spikes about 6" long. These are driven into the sidewalk on the offset line and the elevation of their tops determined by leveling. The difference between the elevation of each spike and the grade of the curb opposite it is calculated. A list of the stations and the distances the spikes are above or below the curb is given to the foreman in charge of the work. These distances should always be transposed into feet and inches (to the nearest $\frac{1}{8}$ ") before being given to the foreman, as it is seldom that the men employed to lay the curbstones have any conception of the meaning of tenths and hundredths of a foot. (See Art. 7, p. 5.)

Where there are trees growing in line with the curbs, a nail can sometimes be set in the side of a tree on the line of the curb as well as at its grade. Points like these, of course, should be set in preference to offset stakes or spikes wherever possible, as there is little liability of the workmen misinterpreting such marks. They can fasten their string directly to the nail and set the curb to agree with it.

Before the curbstones are ordered the surveyor usually measures the distances between trees and locates driveways, and then makes out a list of the lengths of straight, of curved, and of chamfered stones (opposite driveways) to be used on the job. This list is used in ordering the stones, and when they are delivered they should be found to fit the conditions without the necessity of cutting any of them.

276. STAKING OUT SEWERS.—The lines and grades of sewers are sometimes run out in the same way as those described for curbstones. The stakes or spikes (in hard paving) are set on an offset line and the grades figured as described in Art. 275.

Another method which is extensively used is to spike out the center line of the sewer and, from the profile of the street, determine the depth of digging. When the excavation is completed the surveyor again runs out the center line and places batterboards at the proper grade and line. This eliminates the errors which are likely to creep in during the leveling over from the offset spikes as is done in the previous method.

277. STAKING OUT STREET RAILWAY TRACKS.—The lines and grades for street railway tracks are given usually by the use of an offset line of spikes. The spikes are frequently placed on an offset line 5 ft. from the center, or on a line 3 ft. from the gauge of the nearer rail, and at every 50-ft. station or oftener. The differences between the desired elevation of the track and the spikes is calculated, and this information is given to the foreman in charge, usually in the form of printed "grade sheets."

278. RERUNNING STREET LINES AND GRADES.—There is a constant call for lines and grades of streets. All kinds of work, such as the construction of fences, buildings, and street improvements, call for rerunning the street lines and grades.

The work of running out the line is simple enough if the original S. Bs. are in place. It is not uncommon, however, to find that in excavating a cellar on a corner lot the corner bound has been disturbed or that it has been removed entirely; and before the line can be properly staked out it may be necessary to begin at some reliable S. B. farther down the street or even on some other nearby street line.

When the line has finally been rerun it is customary to take and record swing offsets from the corners of the underpinning of several of the buildings located along the street and near to the line. By this record of offsets, then, this street line can very easily and quickly be run out at any future time, and any disturbance of the S. Bs. at the corners can readily be detected. **Several offsets to substantial buildings are often of more permanent value than stone bounds.** In some offices these offsets to

buildings are recorded directly on the street plans. Whenever a street line or grade is rerun full note should be made showing all measurements taken for determining the lines or grades.

Sometimes the original street lines have been so completely obliterated that it is necessary to resurvey them and make a new record plan and description of them and have these new lines "established" by a city ordinance. Such work, for example, has been done by the City of Providence since 1857 when a state law was passed requiring that accurate street lines be marked where the adjacent land was about to be built upon. To properly carry out this law the resurvey of a number of the principal streets was required and the policy then originated has been continued.

When a new building is to be constructed the owner generally requests the City Engineer to define the street grade in front of his property. The surveyor who has charge of this work goes to the place and levels from the nearest B. M. to the site of the new building. He has in his possession the established grade of the street and its cross-section. From these he can compute the elevation of the sidewalk grade at those points along the street line where the grades are desired. On the fence or on stakes set on the side line of the street he marks the grade of the sidewalk at the property line, usually to a hundredth of a foot.

279. REVISING STREET LINES.—In older cities much is being done toward straightening some of the crooked streets, and widening the narrow streets. A survey of existing structures is made and plotted, and the new street lines are then studied with reference to existing conditions. Several proposed lines are sometimes considered and run out on the ground. The line finally selected is carefully run out and offsets to existing structures determined so that it may be definitely located, and the areas of all property taken from each abutter are then surveyed, computed, and described. This layout is then accepted by city ordinance and the necessary construction is made in accordance with the revision.

280. REVISING STREET GRADES.—Sometimes the established grades of city streets have been laid down in the early days of the city, and it is subsequently found that these grades

need revision. In such a case the surveyor will make a profile of the center line of the street, of each curb (if there are any) and sometimes along the side lines of the street. He will also take all necessary elevations on the steps of buildings which lie near the street lines, and a few levels in the front yards of abutting property. From a study of these grades together with a plan of the street the new grade line is laid out so as to affect existing property as little as possible. When this grade line has been accepted it is run out in the usual manner and the street regraded. Stakes for final grading are set to hundredths of a foot.

281. SETTING BATTER-BOARDS FOR A BUILDING. — One of the most common tasks of the surveyor is to set the batter-boards for the excavation and construction of the cellar of a new building. The dimensions of the building and the elevation at which to set it are usually obtained from the architect, although sometimes the elevation of the ground floor of the building is recorded on the plan itself. In a brick or stone building the lines to be defined are the outside neat lines of the building, and the elevation desired is usually the top of the first floor. In the case of a wooden building the line usually given is the outside line of the brick or stone underpinning and the elevation given is the top of this underpinning on which the sill of the house is to rest. Sometimes the outside line of the sill is desired instead of the outside line of the underpinning. There should be a definite understanding in regard to these points before the work of staking out is begun.

Generally there is no elevation marked on the plan and the surveyor is simply told to set the top of underpinning a certain distance above the sidewalk or above the surface of some portion of the lot. If there is an elevation referred to City Datum marked on the plan, he should level from the nearest B. M. and set the batter-boards at the grade given.

The location of the building on the lot is given either by plan or by orders from the architect or owner. Not infrequently the surveyor receives the directions to place the building so that its front line is on line with the other buildings on the street and so that it will stand a certain number of feet from one of the side lines of the lot.

His first work is to stake out the location of the building by accurately setting temporary stakes at all of the corners of the building, e.g., in Fig. 114, at *A*, *B*, *C*, *D*, *E*, and *F*. A stake

FIG. 114. SETTING BATTER-BOARDS FOR A BUILDING.

should be set at *G* also so that the entire work can be checked by measuring the diagonals *AG* and *FB*, and *GD* and *LC*. These checks should **always** be applied where possible. Then the posts for the batter-boards are driven into the ground 3 or 4 ft. outside the line of the cellar so that they will not be disturbed when the walls are being constructed. On these posts, which are usually of 2" × 4" scantling, 1" boards are nailed. These boards are set by the surveyor so that their top edges are level with the grade of the top of the

underpinning or for whatever other part of the building he is giving grades. After the batter-boards are all in place they should be checked roughly by sighting across them; they should all appear at the same level. Sometimes, however, on account of the slope of the ground some of them have to be set a definite number of feet above or below grade.

Then the lines are to be marked by nails driven in the top of these batter-boards. The transit is set up on one of the corner stakes of the house at *A* (Fig. 114), for example, and a sight is taken on *F*. This line is then marked on the batter-board beyond (at *f*) and on the one near the transit (at *a*). If the batter-board is so near the transit that the telescope cannot be focused on it, then point *a* can be set within a hundredth

of a foot by eye if the surveyor will stand outside of the batter-board and sight point *a* in a line determined by point *f* and the plumb-line on the instrument. Then a sight is taken along *AB* and this line is produced both ways and nails set on the batter-boards at *h* and *j*. In a similar manner all of the lines are marked on the batters. These points should be marked with nails driven in the top edges of the batter-boards and there should be some lettering on the boards to make clear which lines have been given. It is well for the surveyor also to show these marks to the builder or inspector and have it clearly understood just what parts of the structure these lines and grades govern.

It is customary to set batters for the jogs in the building as well as for the main corners; but small bay windows of dwellings are not usually staked out, but are constructed from wooden patterns made and set by the builder.

As soon as the excavation is begun the corner stakes are dug out and the building lines are then obtained by stretching lines between the nails in the opposite batter-boards. These batter-boards are preserved until the sills or first floor are in place, when they may be removed.

282. CITY PLANS AND RECORDS.—Every city has a large number of valuable plans and records in its possession. Too frequently these are not kept with anything like the care consistent with the amount of money that has been expended to obtain them. For suggestions regarding the filing and indexing of plans and records see Arts. 483-7, pp. 431-3.

RECTANGULAR COÖRDINATE SYSTEM OF SURVEYING CITIES.

283. GENERAL DESCRIPTION.—It is customary to disregard the effect of curvature of the earth in the survey of a city on account of its limited extent, and to use a system of rectangular coördinates based upon plane surveying. In a coördinate system two arbitrary lines are chosen for coördinate axes, one usually coinciding with some meridian and the other at right angles to it. All points in the city are located by distances from these two axes, these distances being known as X's and Y's, or sometimes

as latitudes and longitudes. The axes are sometimes chosen entirely outside the area to be surveyed, and where they meet (their *origin*) is designated as (0, 0.). Sometimes they are taken through some conspicuous point, such as the tower of the city hall, and are considered as being certain distances from the zero lines as (10 000, 10 000). By either of these arrangements negative values for coördinates are avoided. The coördinates are usually considered positive toward the north and the east, in accordance with the custom of analytic geometry, as is the case in ordinary land surveying. The convergence of the meridians is neglected and all points having the same X coördinate therefore lie on a straight line parallel to the initial meridian and are not all on the same true meridian line.

In the survey of the city of Baltimore (Fig. 115) the origin of coördinates was taken through the Washington Monument in the central part of the city, and the map divided into squares 1000 feet on a side. Each square mile is shown on a separate page of the atlas of the city and these squares are designated by their number north or south, and east or west of the origin, as 1S2W, 3N4E, etc. Any point is designated by the distance in feet north or south, and east or west, as (1000 E, 2000 N).

One of the chief advantages of any coördinate system is that if any point is lost it can be exactly replaced by means of the known coördinates. This would be especially true in case a large section of the city were destroyed by fire.

284. **TRIANGULATION SCHEME.**—The principal points of the survey are usually located by a system of *triangulation*. Prominent points are selected in such positions that the lines joining them form well shaped triangles, i.e., preferably triangles which are not far from equilateral. These points may be signals on tops of hills, church spires, and the like. If the cupola of the city hall, or some such point is chosen as the origin of coördinates it should also be one of the triangulation points. Points which can be occupied by an instrument are in general to be preferred. Such points as steeples or flag poles are definite enough, but where no definite object exists on which to sight the instrument signals are erected for this purpose. Such a signal usually consists of a pole placed carefully over the exact

Baltimore, Md.)

point and braced in a vertical position by other poles forming a tripod. (See Volume II, Chapter I.)

The system of triangles should cover the entire area but should not contain more lines than are necessary to establish a sufficient number of points to control the subsequent work of the survey.

285. MEASUREMENT OF BASE-LINE.— At least one line in the system must be chosen where its length can be very accurately measured; this is called the *base-line*. The lengths of all the other lines are to be computed from this line by means of the measured angles, hence it will be seen how important it is that this line should be measured with great accuracy, and that it should also form well shaped triangles with the connecting triangulation stations.

It should be chosen if possible in some level spot where there are no serious obstacles to the measurement. It is sometimes an advantage to have the ends of the base-line slightly elevated above the general level. The base should be measured with a steel tape the exact length of which is known. The tension should be kept constant by means of a spring balance, and the temperature carefully taken. If the work is done on a cloudy or rainy day the thermometer readings will represent the temperature of the tape much more nearly than when taken in sunshine. The points should be lined in with a transit and the tape held horizontal, or, if the measurements are taken directly from stake to stake, the slope should be determined, by means of a leveling instrument. There should be at least two independent measurements of the line.

286. MEASUREMENT OF ANGLES.— If possible all of the angles of each triangle should be measured by repetition. An "inverting" instrument reading to 20" or to 10" is to be preferred for this work. The angles are repeated at least six times with the telescope direct and the same number of times with the telescope inverted. Several of these sets of readings are made beginning each time with a different initial setting on the circle. For example, if the first setting was at 0° and four sets are to be taken the second would begin with a setting of 90°, and so on. In each case both verniers should be read and the mean

of the two taken. Sometimes the direction of the measurement is changed during the set, the first six repetitions being taken from left to right, and the second six from right to left. In this work it is important that the instrument should be carefully centered over the point, and that the signals are also carefully centered. It is also important to keep the instrument carefully leveled, especially if there is great difference in the angular elevation of the points sighted.

287. Adjustment of the Angles.—The test of the accuracy of the angle measurements is in the "closure" of the triangles. In good work the sum of the angles of a triangle should not differ from 180° by more than about 5 seconds, under fair conditions. After the angles have been measured the errors in the closure of the triangles should be distributed equally among the angles, thus making the sum of the angles in each triangle exactly equal to 180° . If the best results are desired all of the discrepancies due to errors of measurement can be removed by adjusting the system in accordance with the "Method of Least Squares." In ordinary work, however, where the errors have been kept small, the expense of such a computation is not warranted. After all of the angles have been corrected the sides of the triangles may be computed.

288. AZIMUTH.—If the coördinate lines are to run N and S and E and W it is necessary to know the astronomical azimuth of at least one line of the triangulation system before the coördinates can be computed. This may be determined by observation on Polaris as described in Chapter VII, or, in case there are other triangulation points already established in the vicinity, the new system can be connected with them and the azimuths computed from one of these lines. Azimuths are reckoned in this work from lines parallel to the initial meridian, from the south point right-handed, i.e., in the direction S-W-N-E, and from 0° to 360° . When the azimuth of one line is known all of the others may be computed. With the azimuth and length of each line known the difference of the latitudes and departures, i.e., the difference of the X s and Y s of the ends can be found, and with the coördinates of some one

point given, or assumed, the coördinates of all of the other points can be computed as explained in Art. 410, p. 373.

289. SECONDARY AND TERTIARY TRIANGULATION.—After the principal triangles have been completed, forming a system of control, smaller triangles are selected, locating a system of points of lesser importance so far as the survey is concerned. This is called the *secondary system*. Sometimes a third (*or tertiary*) system is introduced, the triangles being still smaller. The tertiary triangles are the ones that would be used for locating the city boundaries, street corners, and important monuments.

It frequently happens that, owing to the large number of angle measurements and the consequent accumulated error, the lengths of the sides of the small triangles become much less accurate than they would be if measured directly; and since many of these lines naturally lie in places where the distance can easily be measured, this measurement should be made as a check, in which case this line becomes a *secondary base-line*. It is a good plan to introduce these measurements frequently, where it can be conveniently done without great expense, in order to prevent the errors of the survey from accumulating unnecessarily.

290. TRAVERSES.—After all of the triangulation is completed the system is extended by running traverses with the transit and tape, from one known point to another. The triangulation points are regarded as fixed and the errors of closure of the traverses are assumed to be entirely in the traverse surveys, the traverses being made to fit in exactly between the triangulation points.

All street lines, or parallel offset lines, are connected with the coördinate system so that the azimuth of every street line in the city may be known, and the coördinates of all important points, such as street corners and lot corners, are computed.

291. METHOD OF LOCATING PROPERTY LINES AND BUILDINGS.—Since the coördinates of the property corners are to be computed it is advisable to locate them by angle and distance from the transit points, for with these data the calculation of the coördinates is simple. The buildings are located from the transit line by methods explained in Chapter VI.

CHAPTER X.

TOPOGRAPHICAL SURVEYING.

292. In making a survey for a topographical map the methods used will depend upon the purpose for which the map is made and the degree of accuracy which is required. But whatever the purpose of the map may be it is not necessary to locate points in the field more accurately than they can be represented on paper, whereas in surveying for an area measurements are made with far greater precision than would be necessary for the purpose of plotting.

While most of the details of topographical surveying can be filled in more economically by the use of the *transit* and *stadia* or by the *plane table* it is thought best to describe here only the more elementary methods, and to reserve the complete treatment of the *stadia* and *plane table* for an advanced work.

293. **TRIANGULATION FOR CONTROL.**— In all cases where the area is large it will be advisable to use a system of triangulation to control the survey, as this is the cheapest method of accurately determining the relative position of a few points which are a considerable distance apart. The details of this triangulation work have already been described under the head of "Rectangular Coordinate System of Surveying Cities," Chapter IX. One line of the survey, the base-line, must be carefully measured. The precision with which the angles of all the triangles must be measured depends upon the use to be made of the map. After the principal triangulation points have been established their positions are plotted on the map. This may be done conveniently by the method of rectangular coördinates described in Art. 283, p. 255. The extension of the system to smaller systems of triangles, called *secondary* and *tertiary*, may be made if necessary. After the triangulation system has been extended far

enough to furnish a sufficient number of points for controlling the accuracy of the map, traverses may be run wherever convenient or necessary for locating topographic details. In all cases the traverses should be connected with the triangulation points at frequent intervals in order that the relative positions of all points may be kept as nearly correct as possible. Where a high degree of accuracy is necessary these traverses should be run with a transit and tape; if, however, errors of a foot or two would not be appreciable on the map it will be sufficiently accurate to use the stadia method of measuring the distances and thus save time. (See Volume II, Chapters I, IV, and V.)

294. LOCATION OF POINTS FROM THE TRANSIT LINE.—

Where a tape is used for measuring the distances, such objects as fences, walls, and buildings may be located as described in Chapter VI, but it will not be necessary to make the measurements with as great precision. Fig. 116 is a sample page of notes of a topographical survey where the transit and tape were used. On city plans, which are frequently drawn to a scale of 40 feet to an inch, a fraction of a foot can easily be shown. On a topographic map the scale is often such that an error of a fraction of a foot becomes insignificant in the side measurements from the transit line, where such errors cannot accumulate. In some cases it may be sufficient to obtain the distances by pacing, and the angles or directions by means of a pocket compass. Locations may frequently be checked by noting where range lines intersect the transit line. In making a series of measurements it is well to take each measurement with a little more precision than is actually needed for plotting, in order to be sure that the accumulated error does not become too large.

In taking measurements the surveyor should constantly keep in mind how the notes can be plotted; this will often prevent the omission of necessary measurements. No matter whether an accurate or only a rough survey is desired **check measurements** should be taken on all important lines.

295. **CONTOUR LINES.**—There are two general systems of representing on paper the form of the surface of the ground.

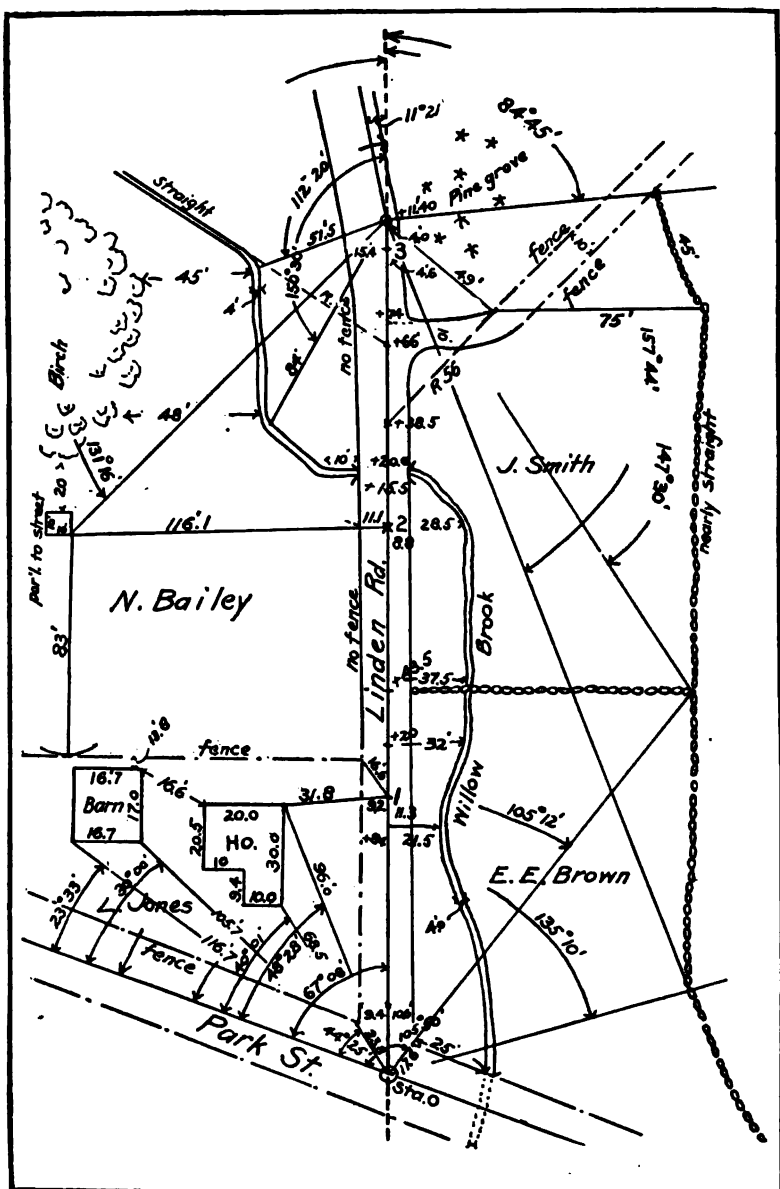

FIG. 116. FIELD NOTES OF A PORTION OF TOPOGRAPHICAL SURVEY WITH TRANSIT AND TAPE.

In one of these systems (Fig. 117) slopes are represented by *hachure lines*, i.e., lines which always run in the direction of the steepest slope of the ground. In the other system (Fig. 118) *contour lines*, lines joining points of equal elevation, are used. In the latter system elevations may be read directly from the map, and for this reason it is much more used by surveyors.

FIG. 117. HACHURE LINES.

FIG. 118. CONTOUR LINES.

A contour line is the intersection of a level surface with the surface of the ground. A clearer conception of a contour line may be obtained from the following. Imagine a valley, or depression in the surface of the ground, partly filled with water. The shore line of this body of water will then be a contour line, since it is the intersection of a level surface with the surface of the ground. If the water stands at an elevation of 50 feet the shore line is the 50-ft. contour. If the surface of the water were raised 5 feet the new shore line would then be the 55-ft. contour. Contour lines if extended far enough will therefore be closed curves, and all of the points on any one contour will have the same elevation above the datum. It is customary to take contours a whole number of feet above the datum, spacing them in regard to height, so as to make the *contour intervals* equal, e.g., a contour may be taken at every 5 feet or every 10 feet of elevation. Since the contours are equidistant in a vertical direction their distance apart in a horizontal direction shows the steepness of the slope.

Fig. 119 illustrates contour maps of simple solids.

FIG. 119. CONTOUR MAPS OF SIMPLE SOLIDS.

206. Characteristics of Contours. — The chief characteristics of contours are illustrated in Fig. 120, and may be summed up as follows.

1. All points on any one contour have the same elevation, as at *A*.

2. Every contour closes on itself, either within or beyond the limits of the map. In the latter case the contour line will not end within the limits of the map but will run to the edge of the map, as at *B*.

3. A contour which closes within the limits of the map indicates either a summit or a depression. In depressions there will usually be found a pond or a lake; but where there is no water the contours are usually marked in some way to indicate a depression, as at *C*.

4. Contours can never cross each other except where there is an overhanging cliff, in which case there must be two intersections, as at *D*. Such cases as this seldom occur.

5. On a uniform slope contours are spaced equally, as at *E*.
6. On a plane surface they are straight and parallel to each other, as at *F*.
7. In crossing a valley the contours run up the valley on one side and, turning at the stream, run back on the other side, as at *G*. Since the contours are always at right angles to the lines of steepest slope they are at right angles to the thread of the stream at the point of crossing.
8. Contours cross the ridge lines (watersheds) at right angles, as at *H*.

FIG. 120. ILLUSTRATING CHARACTERISTICS OF CONTOURS.

Fig. 121 shows a contour across an ordinary city street with

FIG. 121. CONTOUR CROSSING A STREET.

sidewalks and curbstones, the street being located on a steep grade. In order to trace out the position of a contour it is necessary to keep in mind that it is a line all points on which are at the same elevation. It will be noticed that the contour from *A* to *B* crosses the sidewalk in a straight line but not perpendicular to the street line because the sidewalk is sloped toward the gutter. Turning at *B*

it runs straight along the face of the curbstone until it strikes the gutter at *D*, and returns on the other side of the gutter along the surface of the road, the point *E* being where it swings around and travels back toward the other gutter. The other half of the street is similar. If the center of the road is at the same elevation as the top of the curb opposite, then *E* will be opposite *B*. This illustrates how contours run around valleys (gutters) and ridges (crown of street).

If the side of the street to the right (*HF*) were at a lower elevation than the left side then the contour at the point where it crosses the gutter, *F*, would be farther up the road from *E*, i.e., the contour would be unsymmetrical, *EF* being longer than *DE*.

297. RELATION BETWEEN CONTOUR MAP AND PROFILE. —

If a line is drawn across a contour map the profile of the surface along that line may be constructed, since the points where the contours are cut by the line are points of known elevation and the horizontal distances between these points can be scaled or projected from the map. The profile shown in Fig. 122 is constructed by first drawing, as a basis for the profile, equidistant lines, corresponding to the contour interval, and parallel to *AB*. From the points where *AB* cuts the contours lines are projected

to the corresponding line on the profile. Conversely, if the profiles of a sufficient number of lines on the map are given it is possible to plot these lines on the map, mark the elevations, and from these points to sketch the contours as described in Art. 301, p. 276.

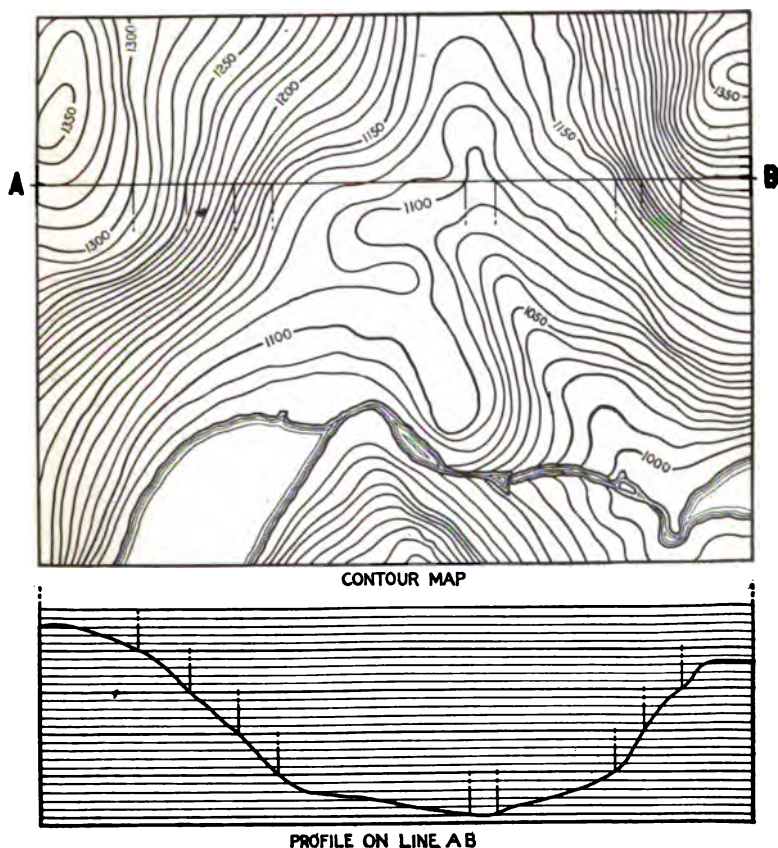

FIG. 122. PROFILE CONSTRUCTED FROM A CONTOUR MAP.

298. RELATION BETWEEN CONTOUR MAP AND SIDE ELEVATION OR PROJECTION.—A photograph of a landscape represents approximately a side elevation of the country. To

construct such a projection from a contour map (Fig. 123), lines

FIG. 123. SIDE ELEVATION CONSTRUCTED FROM A CONTOUR MAP.

are drawn perpendicular to AB , the plane of projection, and tangent to the contours. These tangent points show the limits between the visible and invisible portions of the landscape, the observer being assumed to stand on the line AB and to look in a direction perpendicular to AB .

299. DRAINAGE AREAS. — The drainage area that supplies a stream or pond is limited by the *divide line* which is a line drawn on the ridges surrounding a depression as indicated by the dotted line on Fig. 124. Since the perpendicular to the contour at any point is the direction of steepest slope the direction in which water will flow at any point can be determined at once by examining the contours. On the ridge there is a line (its summit) on one side of which water will flow down one of the slopes and on the other side of which it will flow down the other slope. This line is the *divide line* or *watershed line*.

If a dam were built as shown in Fig. 124, its elevation being 960 ft., the area actually flooded by the water at full height of dam is the area included within the 960-ft. contour, which is indicated by the shaded section. The drainage area for the portion of the stream above the dam is the area included within the heavy dotted line, which follows the line of the divide.

300. SKETCHING CONTOURS FROM STREAMS AND SUMMITS. — The present topography of some parts of the country is due almost entirely to erosion by streams. Consequently the position and fall of the streams give more information regarding the position of the contours than any other topographic features. If a definite position of the contours is desired it will be necessary to obtain the elevation of a few governing points on the ridges as well as the location and elevation of the streams, as shown in Fig. 125. (See Volume II, Chapter VII.)

In sketching in contours from these data it should be borne in mind that the contours cross the stream at right angles to its thread and that they curve around from the hill on either side so as to represent the valley of the stream. The contours are farther apart at the top and bottom of the slope of an eroded hill than near the middle, because in these portions the slope is somewhat flatter. A stream is usually steeper near its source than in the lower portion and therefore the contours are closer together near the source. This is true of most cases but the shape of the contours in any particular case will depend upon the geological formation. Fig. 126 represents the same country as Fig. 125 but with the contours sketched on it, following out the general suggestions which have just been mentioned.

FIG. 124. ILLUSTRATING FLOODED AREA AND DRAINAGE AREA.

FIG. 125. MAP SHOWING THE LOCATION AND ELEVATION OF STREAMS AND SUMMITS.

FIG. 126. CONTOURS SKETCHED FROM THE DATA GIVEN IN THE MAP ABOVE.

301. SKETCHING CONTOURS FROM KNOWN ELEVATIONS.

— A portion of the country can be cross-sectioned as described in Art. 227, p. 206, or profiles can be run on any desired lines as explained in Art. 225, p. 203. From these known elevations contours can be sketched by interpolation. This is usually done by estimation and the principle involved is the same whether the elevations were obtained by cross-sectioning or by profiles.

Fig. 127 illustrates how contours can be sketched from cross-

FIG. 127. CONTOUR SKETCHED FOR CROSS-SECTION NOTES.

section notes. The points at which elevations are taken in the field should be so chosen that the slope of the ground is practically uniform between any two adjacent points. Then by simple interpolation the contours may be accurately sketched. This interpolation may be done by geometric construction, but for most topographic work it is accurate enough to interpolate by eye.

302. MISTAKES IN SKETCHING CONTOURS. — Fig. 128 shows several examples of impossible and incorrectly sketched contours; the streams are assumed to be correctly located. The numbers on the figure refer to the tabulation made in Art. 296, p. 268, and will assist in detecting the type of error present.

FIG. 128. CONTOURS INCORRECTLY SKETCHED.

303. LOCATING CONTOURS. — Contours are often most economically located by means of the *transit and stadia* or by an instrument called the *plane table*.* In this chapter, however, only those methods will be considered which call for the use of the transit and tape.

* A brief explanation of the principles of the Stadia will be found in Appendix A, p. 517 of this volume. A complete discussion of the Stadia and the Plane Table will be found in Volume II, Chapter IV.

304. Locating Contours by Cross-Sections. — A very common as well as expensive method of locating contours is that of taking cross-sections. Elevations on the surface of the ground are usually taken to tenths of a foot. From these elevations the contours may be sketched by interpolating between these known elevations as explained in Art. 301. The accuracy may be increased by taking a larger number of intermediate points. The size of the squares used should depend upon the roughness of the surface.

305. Locating Contours by Profiles. — In some cases where the ground is fairly smooth it is sufficient to take a few profiles on known lines, not necessarily at right angles to each other. These lines are stationed and elevations are taken at every full station and at the points of marked change in slope. From these data the contours are sketched on the map by interpolation as described in Art. 301.

306. Locating Points on the Contours. — Where the contour interval is small, say one or two feet, and the topography is to be determined with considerable accuracy, it is advisable to find, in the field, points actually on the contours and thus avoid the errors of interpolation. The rodman moves up or down the slope until the rod-reading indicates that the foot of the rod is on a contour. The position of the rod may then be located by an angle and a distance from some known line, the distance being taken with a tape.

307. Locating Contours by the Hand Level. — A more rapid but less accurate way of putting in contours is by means of the hand level. The work is done by making profiles of lines whose positions on the map are known. A point on some contour is found in the following manner.

The first step to take is to measure to the nearest tenth of a foot the distance from the ground to the eye of the leveler, which may be, say, 5.4 ft. If the B. M. is at elevation 143.43 and it is desired to locate a point on the 140-ft. contour, the rodman holds the rod (or a tape) on the B. M. while the leveler attempts to place himself on the 140-ft. contour. When he is on the 140-ft. contour the elevation of his eye (H.I.) is 145.4

and the rod-reading at the B. M. must be $145.4 - 143.43 = 1.97$, or 2.0 to the nearest tenth of a foot. The leveler therefore travels along the line on which the point is to be located until he reads 1.97 on the rod. His feet are then on the 140-ft. contour, the position of which is located from some known point on the line. Sometimes this is done by measurement and sometimes by pacing. A point on the 145-ft. contour could have been located first by applying the same principle, but if the 140-ft. contour is established it is very easy to locate a point on the 145-ft. contour as follows. The distance from the leveler's feet to his eye being 5.4 ft., if he stands on the 140-ft. contour and reads 0.4 ft. on the rod, the bottom of the rod must be on the 145-ft. contour. By trial then the point is found where the rod reads 0.4 ft.* Then the leveler walks up the hill and, standing on the point just found, places the rodman on the next higher contour by the same process.

In working down the hill to locate the 135-ft. contour, if the leveler is standing on the 140-ft. contour, the rod will be on the 135-ft. contour when it reads 10.4 ft. Or, when the 140-ft. contour has been found by the leveler the rodman comes forward and holds the rod on this spot and the leveler backs down the hill until he reads 0.4 ft. on the rod; he is then standing on the 135-ft. contour. Some surveyors prefer to cut a stick just 5 ft. long and hold the hand level on the top of it in taking sights.

The points thus found at regular contour elevations are then plotted on the corresponding lines and the contours sketched by joining points of equal elevation. Where the lines which are profiled are far apart or where the country is very rough it is frequently necessary to obtain the correct position of the contours, to locate extra points on them between these profiled lines. The extra points are located by right-angle offsets from the lines. Most of this work is plotted in the field upon paper ruled in small squares to facilitate sketching. Where practicable it is always well to sketch the contours in the field rather than in the office.

* For very rough work sometimes the rod is not used, the leveler simply estimating where the rod-reading will come on the rodman's body and placing him so that his feet will be on the proper contour.

308. LOCATION OF STREAMS AND SHORE LINES. — Streams or shore lines of ponds may be very rapidly located by stadia measurements. If the shore lines are to be located by tape measurements, however, a convenient way is to run a transit line approximately parallel to the general direction of the shore line, and to take perpendicular offsets at regular intervals and at all points where there is a marked change in the direction of the shore line, as was done in the notes in Fig. 53, p. 104.

309. CONTOUR PROBLEMS. — There are many surveying problems involving earthwork which can be worked out approximately by use of a contour map. As a rule the smaller the contour interval, the more accurate will be the result of such work. Contour studies occur in a variety of problems, so numerous that it would be useless to attempt to cover the subject fully. Three typical problems, however, are illustrated and explained; and these contain the essential principles applicable to practically all contour studies.

310. EXAMPLE I. — (Fig. 129). Given a contour map, the surface being represented by contours shown by full lines, a plane (extended indefinitely) is passed through the straight lines *AB* and *CD*, which are level and parallel, *AB* being at elevation 12.5 and *CD* being at elevation 40. It is required to find where this plane intersects the surface, and to shade the portion which is above the plane.

Since the proposed surface is a plane, contours on it will be parallel to *AB* and *CD*. The elevations of *AB* and *CD* being known, other contours, such as *ef* and *gh*, can be interpolated between *AB* and *CD*. Their interval is made 5 ft. the same as the contour interval for the original surface. Evidently the point where any of these parallel lines crosses an original contour of the same elevation, as *j*, *k*, *l*, *m*, or *n*, is a point on the intersection of the plane with the surface. Joining these points gives the line of intersection of the plane with the original surface, which is indicated by the heavy full line on the figure. Such points as *q*, *s*, or *t* are determined by interpolation. Intermediate contours are drawn at one-foot intervals between the original surface contours; corresponding lines are interpolated between the straight contours which show the plane; additional

intersections obtained, and in this way the point p is determined. Again it will be seen that point t , with reference to the parallel straight contours, is at about 18.5; with reference to the original

FIG. 129.

contours, it will be seen that wt is about three-tenths of wr , the distance between contours, and this makes the elevation of point t equal to 18.5.

311. EXAMPLE 2.—(Fig. 130.) Given a contour map which includes a road, and on which the original contours are represented by full lines. It is desired that all of the road between A and B shall be visible from the ground at point C . Sketch on the map and shade the portions which will have to be cut down to fulfill this requirement.

The general method of solving this problem is to sketch a new set of contours on the map, which will represent a uniform

slope from *C* to the nearer edge of the road. Everything that is above the surface represented by these new contours must be cut away.

First draw lines, such as *Ca*, *Cb*, and *Cc*, the points *a*, *b*, and *c* being points on the upper side of the road between which it may be assumed that the slope is uniform (Art. 301, p. 276). Along these lines interpolate points which will lie on the uniform slope from *C* to the road and also on the regular 5 ft. intervals which correspond to the contours. For example along the line *Ca*

FIG. 130.

from the summit which is at elevation 89 to the road at *a* which is at elevation 55, there is a drop of 34 ft., or a little less than 7 contour intervals. Points *e*, *f*, *g*, *h*, etc. are therefore plotted so as to divide *Ca* as follows: *ea*, *ef*, etc., are each $\frac{5}{8}$ of *AC*, and the upper division is $\frac{4}{8}$ of *AC*. Similarly points *i*, *j*, *k*, etc., are plotted along the line *Cb*, but the point *b*, being at elevation 56, is plotted so that the distance *ib* is four-fifths of the other distances *ij*, *jk*, etc. When these points have been plotted on all of the necessary diagonal lines, the contours representing a uniform slope from *C* to the road are sketched on the map as shown by the dotted lines on the figure. The points, such as *m*, *n*, or *r*, where the new contours cut the old contours of equal elevation, are points of "no cut and no fill." A line connecting these

points encloses portions of either cut or fill. The shaded portions of the figure, where the new contours are nearer C than the corresponding old ones, represent the portions where it will be necessary to excavate to the surface represented by the dotted contours. In the central portion of the figure, from point c to p , the road can already be seen.

312. EXAMPLE 3.—(Fig. 131.) Given a contour map on which are shown the two side lines of a road, the contours being represented by full lines. The road is to be built on a 4% down grade starting at *A* at elevation 55. Scale 1 inch = 150

FIG. 131.

feet. Side slopes of road to be $1\frac{1}{2}$ horizontal to 1 vertical. It is desired to sketch the new contours on the slopes of the road, to sketch on the map the top and foot of slopes, and to designate the portion in embankment and the portion in excavation.

First, the new contours which are to cross the road are plotted at *ab, cd, ef, gh*. These will be 125 ft. apart, as a 4 % grade falls 5 ft. in a distance of 125 ft. If the road is assumed to be level on top, then these lines will cross the road at right angles to its general direction as shown in the figure. From points *a* and *b*, on either edge of the road, the new contour

lines will follow along the slope, e.g., the line ao represents the new 50 ft. contour. Where this contour ao passes point c it is just 5 ft. above the road. Since the slope of the cut is $1\frac{1}{2}$ to 1, then the distance cut from c must be $1\frac{1}{2} \times 5 = 7.5$ ft.; opposite e it is 10 ft. below the road and similarly the distance out from e must be 15 ft. Where this new 50 ft. contour meets the old

FIG. 131.

50 ft. contour at a , is a point at the top of the slope. Similarly all of the new contour lines, which are represented on the figure by dash lines are plotted and their intersections with the corresponding contours of the original surface give points of "no cut" or "no fill," or top of slope (in excavated portions) and foot of slope (in embankment portions). These lines are shown in the figure by heavy dotted lines. Where this heavy dotted line crosses the road it marks a "no cut" and "no fill" line, i.e., the road bed cuts the surface of the ground.

CHAPTER XI.

MINE AND MOUNTAIN SURVEYING.*

313. **GENERAL REMARKS.** — In this chapter the limitations and difficulties met with in surveying a mine will be pointed out and some of the instruments and methods generally used will be described. As rocky and precipitous mountain regions are more the home of metal mining than of any other industry, the special difficulties of surface surveying in such localities will also be considered. Lastly, the methods of establishing the boundaries of mining claims in United States territory will be briefly described.

Two of the principal objects to be accomplished in accurate mine surveying are the locating of the ownership boundaries underground and the laying out of passageways so as to connect with one another, thereby facilitating the working of the mine. Such passages are usually highly inclined and therefore it is frequently necessary to use entirely different methods from those employed in ordinary surveying.

314. **DEFINITIONS OF MINING TERMS.** — The following terms are in common use in mine surveying.

Adit. An approximately horizontal underground passageway running from the surface into the mine workings and used only for drainage and ventilation.

Apex. The portion of the surface of the undisturbed rock formation which is included between the walls or sides of the mineral deposit.

Bed. A stratum in the earth's crust which has been formed or deposited in an approximately horizontal layer.

* This chapter was written by Blamey Stevens, M. Sc., Mining Engineer, Seattle, Wash.

Compartment. One of the smaller passageways of a large shaft divided by timber partitions. Fig. 134 is the plan of a three compartment shaft.

Connection. A passageway which is driven from one accessible part of the mine to another.

Cross-cut. A horizontal passageway across or approximately at right angles to the strike.

Dip. The inclination of any rock plane to the horizon.

Drift. A horizontal passageway along, or approximately parallel to, the strike.

Fault. A fracture in the earth's crust along which slipping or shearing has occurred.

Floor. The bottom of the passageway or of a seam or bed.

Heading. Any preliminary passageway driven to explore the mine or to facilitate the future operations.

Heave. The distance between the two parts of the same vein which is divided by a fault, measured along the strike of the fault.

Levels. Horizontal passageways run at different levels along the deposit or adjacent to it for working the mine.

Manhole. A small passage from one level into the next level above or below, or into stopes.

Mill-hole. A passage between a stope and a level through which the ore is conveyed.

Outcrop. That portion of the vein which is exposed on the surface of the ground.

Pitch. The direction (in azimuth and altitude) of the longest axis of an ore body.

Prop. A piece of timber which prevents any rock in the roof from falling.

Raise. A passage driven steeply upward from any portion of the mine.

Roof. The top of a passageway or of a seam or bed.

Room. A place other than a passageway from which material has been extracted. The term usually refers to bed deposits.

Seam. A bed of mineral or a small vein.

Shoot. A gate used for drawing off broken ore from a stope or raise. Also an ore body within a vein.

Stopes. Rooms formed by the excavation of ore above or below a level, sometimes filled with broken ore or rock.

Strike. The direction (bearing) of a horizontal line in the plane of a deposit. The strike is always at right angles to the dip.

Stull. A piece of timber wedged in crosswise between the side walls of a passageway.

Throw. The vertical distance between the planes representing two parts of the same vein which is divided by a fault. The term is used only in regard to nearly horizontal deposits.

Tunnel. A horizontal working passageway from the surface to the mine.

Vein. (Also *lode*, *ledge*, *lead*, etc.) A mineral body of the flattened shape. These terms are also applied to mineral bearing faults.

Wall. The rock on each side of the mineral body. The upper wall is called the "hanging wall," and the lower the "foot wall."

Winze. A subsidiary shaft not starting from the surface.

MINING INSTRUMENTS.

Owing to the confined nature and steep inclination of many of the passages through which survey lines have to be carried, specially constructed instruments are necessary.

315. MINING TRANSITS. — In modern mining, all the accurate angle measurements are taken with a transit, the details being filled in with a *miner's dial* or other light compass instrument. Several forms of transit are designed for mining and mountain work. The essentials are lightness and adaptability for measuring accurate azimuths of nearly vertical or of very short sights. A high power telescope is more necessary than for ordinary surveying, as the small variation of the line of sight means a large error in azimuth when sighting with high altitudes.

With an ordinary transit one cannot take a downward sight more steeply inclined than 55° or 60° to the horizon. For sighting larger angles of depression various devices have been used by which telescopic sight may be taken over the edge of the horizontal circle of the instrument. This is commonly done by attaching

FIG. 132. MINING TRANSIT WITH SIDE TELESCOPE.

(From the catalogue of C. L. Berger & Sons, by permission.)

an auxiliary telescope to the side or to the top of the ordinary engineers' transit so that the instrument will afford all the advantages of the ordinary transit and also make it possible to sight down a vertical shaft.

Fig. 132 316. **ECCENTRIC TELESCOPES.**—Fig. 132 shows a mining transit in which the auxiliary telescope is attached to an end extension of the horizontal axis. Such an instrument is known as a *side telescope transit*. The distance and direction between the centers of the main and auxiliary telescopes is called the *eccentricity*. In this case it is measured along the horizontal axis. Fig. 133 shows an *eccentric bearing mining transit* which has an extra pair of supports for the horizontal axis. The eccentricity in this case is also measured horizontally but at right angles to the horizontal axis. In the type of transit known as the *top telescope transit* the auxiliary telescope is mounted on the top of the main telescope. The eccentricity in this case is at right angles to the horizontal axis and to the main telescope.

Fig. 134 317. **Correction for Eccentricity.**—The eccentricity of a mining transit has to be allowed for when either of the auxiliary attachments is made use of. The correction may be made by regarding the line between the centers of the eccentric and main telescopes as one of the lines of the traverse. Instead of making this correction as a link of the traverse it may sometimes be more convenient to sight the auxiliary telescope to an auxiliary point which bears the same relation to the station required to be observed as the center of the auxiliary telescope does to the center of the main telescope. It is also possible to make a correction to apply to the bearing of the auxiliary telescope which renders it the same as the bearing from the main telescope would be if it were possible to make the observation with it. In some forms of instrument the correction may be eliminated by using the instrument in both the direct and reversed positions.

318. **Relative Merits of Attachments.**—In comparing the relative merits of the various forms of attachment it must be remembered that the object to be accomplished is to transfer the meridian accurately from one station to another, these stations being close together in plan, and distant in elevation.

The side telescope has the merit of being easy to work. Since

this telescope is easily detached the transit need not be encumbered with it when the main telescope can be used, which is the case in the majority of the observations. When this attachment is used the effect of eccentricity in the measured azimuths is easily allowed for. Accuracy may be obtained by reversing the instrument and by leveling the horizontal axis each time by means of the *striding level*. This is a sensitive spirit level having two V-shaped bearings so that it can be set on top of the horizontal axis; it can be lifted and turned end for end.

The eccentric bearing telescope, though not so convenient to use as either of the other forms of mining transit, has advantages for very accurate work, since the telescope is placed symmetrically with respect to the horizontal axis and its supports. It also has the advantage of greater rigidity and of being adjusted directly, like an ordinary transit, instead of indirectly. The correction for eccentricity is simple, and the telescope may be reversed in its horizontal bearings and used in connection with a striding level. It has, however, the disadvantage of being more bulky, which is objectionable in ordinary work, and also the disadvantage that in a dirty mine grit is liable to accumulate in the horizontal bearings while the telescope is being changed from one set of bearings to the other.

With a top telescope the instrument cannot be reversed. With such a transit the correction for eccentricity is only applied to altitude readings. For rapidly conveying an azimuth where extreme accuracy is not paramount this type of attachment is useful.

319. ADJUSTMENTS OF MINING TRANSITS. — It is assumed that all ordinary adjustments of the transit have been made. In addition the adjustment of the object slide (Art. 77, p. 60) is of unusual importance, because often in mining work the azimuth has to be transferred over very short sights. Exceptional care must be taken to get the horizontal axis of the telescope truly horizontal and the line of sight exactly perpendicular to it.

The side telescope is generally adjusted by first making the line of sight parallel to the axis of the telescope tube. This is done by the cross-hair adjustment and the aid of a pair of fixed wyes in which the tube is rotated; it is the same adjustment as for the level, Art. 121, p. 89. It is assumed that the instrument

TELESCOPE IN ECCENTRIC BEARINGS.

FIG. 138. MINING TRANSIT WITH ECCENTRIC BEARING TELESCOPE.

(From the catalogue of C. L. Berger & Sons, by permission.)

maker has made the optical axis parallel to the axis of the tube, but the accuracy of this should be tested.

Secondly, the line of sight is made parallel to that of the main telescope. It is first brought into a vertical plane parallel to the vertical plane of the main telescope by means of the adjusting screws on the vertical trivet plate of the side telescope, the sight of each telescope being taken to the same very distant object. If it is not convenient to sight on a distant object, a piece of paper with two vertical marks connected by a horizontal line may be used, the distance between the marks being equal to the distance between the telescopes. This piece of paper should be set at right angles to the line of sight and not too near the instrument. The vertical cross-hair of the main telescope is sighted at one point by means of the clamp and tangent screw of the plates and then the vertical cross-hair of the side telescope is sighted at the other point by means of the trivet plate adjustment on the side telescope.

The side telescope and main telescope are then brought into the same plane at right angles to the vertical plane as follows:—the horizontal cross-hair of the main telescope is sighted at some point, preferably a distant one; then the horizontal cross-hair of the side telescope is sighted at the same point by means of the tangent screws on the side telescope.

As the adjustment of the side telescope is not direct, but is made by comparison with the central telescope, the instrument should be reversed when accurate observations are required. This also eliminates the correction for azimuth due to eccentricity.

The striding level should be used in both of its positions; i.e., with the main telescope direct the striding level is used in both positions and two azimuths are read, and with the telescope inverted the striding level is again used in both positions and two more azimuths are read. The mean of the two readings of each pair gives two mean lines of sight which are symmetrically related to the vertical plane passing through the two station points and the correct azimuth reading is therefore the mean of these two azimuths. There is a small correction to be applied to the mean of the altitude readings but this is not usually of any importance.

The top telescope is adjusted in much the same manner as the side telescope.

In the eccentric bearing telescope no extra adjustment is necessary other than that of the bearings of the horizontal axis when the telescope is used in the eccentric position. This is done with the striding level, which is also used in taking accurate sights, the telescope being reversed by lifting out of the horizontal bearings and turning the horizontal axis end for end. As no attempt is made to adjust the two pairs of horizontal bearings to be absolutely parallel, the foresight and backsight in ordinary work should both be taken with the horizontal axis in the same pair of bearings.

320. INTERCHANGEABLE SIDE AND TOP TELESCOPE.—Some instruments are made with an interchangeable telescope which can be attached at either the top or the side of the main telescope, according to whether horizontal or vertical angles are being measured. In such an instrument no correction for eccentricity of the auxiliary telescope is necessary, and it is arranged so as not to require readjustment when changed from side to top or *vice versa*.

321. COMBINED SOLAR ATTACHMENT AND TOP TELESCOPE.—A special top telescope is sometimes made to do the duty of a solar attachment; but it is now generally admitted that better meridian determinations can be made by direct, single observations with the main telescope, and the surveyor is advised not to get any such complex attachment for mining work.

322. USE OF THE ORDINARY TRANSIT IN MINING SURVEYING.—Where a special attachment is not to be obtained, or when the auxiliary telescope is too small for accurate work, the ordinary transit can be used in such a manner as to accomplish the same result as an eccentric telescope instrument. (Art. 316). The instrument, firmly screwed on to the tripod, is inclined over the shaft at an angle just sufficient for the line of sight to clear the horizontal plate. It is then braced in position by such rigid supports as the circumstances afford, and the head of the instrument is rotated so that the horizontal axis of the telescope becomes truly horizontal, as determined by a striding level, while the telescope is sighting in the desired azimuth. One or more station points are then set out down the mine and one each way on the surface, all in the same azimuth, and these are respec-

tively connected with the mine and surface surveys. All errors of adjustment may be eliminated by repeating sights with the telescope in the direct and the reversed positions and by reversing the striding level each time and taking the mean position of the four points so set.

An attachment which is very necessary in performing some of the work required of mining transits is the *diagonal* or *prismatic eyepiece*. This makes it possible to take any sight whatever above the horizon, and being a convenient instrument to use and not requiring any adjustment, it should be carried by every mine surveyor. ✓

323. COMPASSES USED IN MINES.—The transit has taken, to a great extent, the place of the old miner's dial in which the compass was the main feature. This is partly because, in modern mines, so much heavy machinery is used that the compass needle cannot be depended upon, even to its ordinary degree of accuracy.

Compasses, however, serve a useful purpose in general mining work. They are made in many sizes and of different design. A compass with a plain needle is to be preferred to one with a swinging card, since the former can be brought to a central position more quickly and is more accurate by reason of the lesser amount of weight on the center bearing. Compasses may be used for reconnaissance surveys and also for filling in the details of a mine from the main stations. A mining compass should be capable of sighting fairly high altitudes above or below the horizon, and a sighting clinometer attachment for measuring vertical angles is very convenient as it obviates the use of any other instrument. A small modern mining dial mounted on a light tripod fulfills all these conditions. The *hanging compass and clinometer* is made so as to be hung from a wire stretched between two station points thus rendering sighting unnecessary, but it is not much used.

The circumferenter is a dial with an additional revolving plate which makes it possible to measure angles independently of the compass needle. Other improvements have so modified the instrument that it differs little from a light mining transit with an auxiliary top telescope instead of the main telescope.

A mounted compass is more accurate than one simply held in the hand, but any hand compass may always be mounted when the conditions permit. Perhaps the best form of compass for details and reconnoissance work is the Brunton mining dial. The observer looks down on this instrument and the line of sight is reflected upward toward him by a hinged mirror so that the object and the compass box are seen simultaneously. A clinometer is attached, which is suitable either for measuring dips or sighting inclinations.

324. MAGNETIC SURVEYING. — Ore of a magnetic nature has often been discovered by local variations of the compass needle and by the dipping needle, a special self-plumbing form of which is made for the use of miners. More accurate methods have been devised by Swedish engineers who make charts of magnetic intensities.

The latter method depends in principle on the measurement of the horizontal and vertical components of magnetic intensity. The horizontal intensity is found by noting the angle which a horizontal compass needle is deflected by the introduction of a magnet placed in the swinging plane of the compass needle and a fixed distance from it measured at right angles to the position of rest of the needle before the magnet is introduced. This is compared with the deflection produced by the magnet alone when there is no ore body affecting the needle. The vertical intensity is found by the deflection of a needle swinging in a vertical magnetic east and west plane. The deflection is against a gravity righting moment, the needle being previously weighted so as to balance the vertical component of the earth's magnetism.

More detail may be obtained by rendering both the compass and dipping needle astatic, i.e., by placing them in a framework about which permanent magnets are fixed so as to just neutralize the ordinary magnetism of the earth. The lines of force due simply to the magnetic ore body may then be mapped together with the intensities of these forces as determined by the principles previously cited. We may generally take it for granted that the magnetic axis of the ore body is parallel to the earth's magnetic lines of force. As we probably also have some general notion of the strike and dip of the ore shoots it will be possible in many

cases to determine approximately the position of the ore body even though it is covered to a considerable depth.

The above methods may be used in a limited way underground. Sometimes an artificial ore body made of a large permanent magnet is used for determining the length and direction of a required connection where traversing is not entirely to be relied upon.

UNDERGROUND SURVEYING.

325. TRANSFERRING A MERIDIAN INTO A MINE BY USE OF THE TRANSIT. — Only a moment's thought will convince the student that some difficulty must be experienced in accurately transferring the meridian to the bottom of a narrow shaft several hundred feet in depth. The ordinary method of transferring a meridian into a mine is to set up the transit at a station fixed at the mouth of the shaft and, after taking a backsight on the previous station on the surface, to take a foresight down the shaft, the line of sight being made as much inclined to the vertical as possible. Having ascertained the intervening distance, the transit is set up at the bottom station, a backsight taken on the top station, and the survey then carried into the galleries of the mine. The top and bottom stations are not always the surface and bottom of the shaft, although for simplicity they may be referred to as such in this chapter.

In sighting from both ends of the same highly inclined line it will be found that errors of meridian due to the line of sight not being perpendicular to the horizontal axis are eliminated if the readings are made with the telescope in the same position at both sights, whereas errors of meridian due to the horizontal axis not being perpendicular to the vertical axis are eliminated if the readings are made with the telescope direct when at the top and reversed when at the bottom of the shaft, or *vice versa*. Obviously both are eliminated when the direct and reversed position are used at both the top and the bottom of the shaft and the mean readings taken in each case.

When it is impossible to sight up a shaft on account of its being too wet, two or more points can be set in line at the bottom

of the shaft by means of the instrument when at the top, and these will determine a line of known azimuth at the bottom of the shaft.

The great importance of having the horizontal axis truly horizontal should not be overlooked and elimination of the errors by reversing and taking mean readings should not be relied upon without the aid of the sensitive striding level which also eliminates any error due to the vertical axis not being truly vertical.

In some cases a wire is stretched horizontally across the bottom of the shaft and as far back into the workings as possible, the wire being carefully aligned by the instrument at the top. This method may admit of even more accuracy than that of taking a backsight to the surface from a station established in the bottom of the mine. Errors due to a slight inclination of the horizontal axis are not important when this method is used for a vertical shaft, and for that reason it is also useful in cases where a sensitive striding level is not to be had. The effect of a slight inclination of the horizontal axis is simply to shift the line slightly to one side but parallel to the true position.

When no extra telescope or eccentric bearings are to be had, an ordinary transit with a prismatic eyepiece attached may be used to drop the meridian down a vertical or highly inclined shaft, provided it is not so wet as to prevent sighting upward from below. To accomplish this a thin wire is stretched horizontally across the top of the shaft at a known azimuth; the wire should be prolonged one or both ways in order to give a good base-line. Two points may be fixed at the top of the shaft if preferred. The transit is then set up on the bottom and it is brought by trial into the same vertical plane as the wire. The striding level is used in both positions and the transit is used in both the direct and reversed positions to eliminate errors.

It is to be noted that in mining and mountain work slight errors of altitude measurements occur in sighting up steep inclines owing to the refraction of the atmosphere, but this is so slight as not to affect the transfer of the meridian at all.

326. PLUMBING THE MERIDIAN DOWN A SHAFT.— To the mine surveyor the plumb-line is an instrument of precision, excelling even the transit, and under most conditions, the work of transferring the meridian down a mine can be accomplished more accurately by means of the plumb-line than by any other method accessible to the surveyor.

The method usually followed is to suspend two bobs from the staging above the mine so that a horizontal line in their plane can be sighted both from above and from below. The transit is set up both above and below on this line and thus an azimuth connection is established between the surface and the workings. Sometimes a much longer base-line than can be directly sighted can be obtained by plumbing down at the corners of a shaft as shown in Fig. 134. Points *A* and *B* have been plumbed down

FIG. 134. TRIANGULATING AT THE BOTTOM OF SHAFT.

and, by the triangulation method there indicated, a connection with the underground traverse can be established. In this triangle the angles should be chosen so as to give a minimum error to the meridian. All kinds of drafts in the shaft should be avoided during the alignment at the bottom. No cages or skips should be run and drafts from the passages leading to the shaft may have to be damped with sheets of canvas.

No lateral streams of water should impinge on the plumb-lines; in fact it is desirable that no water at all should drop in their vicinity.

The best plumb-line for this work is one made of wire. Annealed copper wire is most flexible, but soft steel or piano wire being thinner will be less affected by drafts and will also stretch less. The plumb-bob should not weigh less than five pounds and should be heavier for a deep shaft. A good working weight is one-third of the load at which the wire will break.

The plumb-bob is hung in a bucket or a barrel of viscous liquid so as to bring it to a standstill in the shortest possible time. The shape of the plumb-bob is of importance in this respect

and the form shown in Fig. 135 is a good one, since it prevents rotary as well as lateral oscillations. It should hang near the top of the vessel as the wire will be in a high state of tension and will stretch considerably. A mark should also be made on the wire showing how far the bob is above the bottom of the vessel.

The liquid must be a true one (not a mud or slime) and it must be neither too limpid nor too viscous; for in the former case it will not stop the oscillations within a reasonable period, and in the latter the bob may not reach the central position quickly enough. The amplitude of the vibrations of the plumb-bob decreases in a fixed ratio with equal increments of time, and the viscosity of the fluid should be such as to make each oscillation, say, about one-quarter of the preceding. The ratio of decrease during equal increments of time is nearly independent of the length of the plumb-line and of the amplitude of the oscillations if the resistance is purely viscous. This law makes it possible to select the fluid above ground, with the aid of a short length of wire attached to the bob; it applies only when the bob swings through a very small arc so that the resistance is wholly viscous. It may be noted that the period of oscillation varies roughly as the square root of the length of the plumb-line, the same as for a pendulum swinging in air.

Sometimes it seems impossible to stop all oscillation of the pendulum. This may be on account of the wobbling of the vertical currents of air in the shaft. Perfect rest however is not necessary. The telescope may be directed at a mean position by placing a graduated scale immediately behind the wire and taking readings on it through the telescope when the wire reaches the limits of its oscillation.

If the shaft is wet the vessel should be covered with a sloping lid having a hole in it of an inch or so in diameter so that the wire can swing freely. In order to obtain as long a base-line as possible the wire should be hung as near to the casing of the shaft

FIG. 135. TYPE OF PLUMB-BOB USED IN PLUMBING MERIDIAN DOWN A SHAFT.

as is consistent with the precaution that it shall be perfectly plumb. It should be carefully examined along all its length to make sure that there are no obstacles to interfere with it. In some cases it may be sufficient to pass a lighted candle around the wire at the bottom and observe any obstacles by sighting from the top. The distance between the wires at the bottom and top of the shaft should always be measured and compared, as this gives the best test of the accuracy of the plumbing operation. If four lines, one in each corner of the shaft, are hung instead of two an accurate check or measure of the errors is possible.

When once the plumb-lines are hung the meridian may be transferred to all the levels of the mine once and for all time, so that a little extra precaution and time given to this operation are worth while. The surveyor should always keep in mind the fact that in plumbing the meridian down the mine the direction of the meridian is of much more importance than the actual position of the points themselves, because an error due to an incorrect direction of the meridian may be multiplied many hundreds of times in carrying the traverse through the mine (Art. 348, p. 317).

327. TRANSFERRING A MERIDIAN INTO A MINE WHEN THERE ARE TWO SHAFTS.—The above methods presuppose that the mine has so far been opened only by one shaft. If there is a second shaft or an adit, it is, of course, only necessary

FIG. 136.

to plumb or otherwise transfer the position down each shaft; the computed distance between these points then becomes a base-line of substantial length. In Fig. 136 the traverse *ABCD* is run

out on the surface to connect the two shafts at *A* and *D*. The points *A* and *D* are plumbed down the shafts and the corresponding points *A'* and *D'* established at the bottom. An underground traverse *A'G'F'E'D'* is then run out. In the surface traverse the length and azimuth of *AD* and in the underground traverse the length and azimuth of *A'D'* are missing. The horizontal length and azimuth of each of these lines can be determined from their respective traverses as explained in Art. 397, p. 366. The surface traverse is referred to the true meridian, and, since nothing is yet known in regard to the direction of the meridian in the mine, the underground traverse is referred to an assumed meridian. The true azimuth of *A'D'* is the same as the azimuth of *AD*, provided the plumbing down the shaft has been accurately done. The difference between the true and assumed azimuths of *A'D'* is a correction to be applied to the azimuths of all of the lines of this underground traverse.

328. UNDERGROUND TRAVERSES. — Surveying in a mine is necessarily a process of traversing, for only the working passages are available for lines of survey. The line of traverse is not always in the center of the passage but is often varied from it in order that the longest possible sight may be taken. In the tortuous passages of a mine it is frequently necessary to take very short sights on the main traverse and since the azimuth is transferred to distant connections through these short lines great care should be exercised; and instrumental errors should be eliminated by reversing the telescope and using the mean of the two results. The positions of the walls of the passages are noted as the work proceeds and are sketched in approximately on the plot. After the main traverses have been run, the surface boundaries, if touched, may be accurately established underground and the stopes and working places surveyed by more convenient and less accurate methods, from the stations already established.

It is often very convenient in underground work to take the azimuth from an estimated general direction (or strike) of the vein; for the direction of the meridian is of no importance in the actual working of a mine, while the direction of most of the passages will usually vary only a few degrees from the strike, and thus all traverse calculations are simplified.

A speedy and convenient manner of running an underground traverse is to use three tripods having leveling heads and centering plates like those of the transit. The transit fits on to any of these heads and while it is attached to one of them the other two are surmounted by *lamp targets* in which the sighting center has exactly the same position as the sighting center of the transit would have if set on the same tripod. These tripods are placed vertically over or under the stations and the transit is attached to the middle one. When the transit head is moved from the middle to the foremost tripod a target takes its former place and the hindmost tripod is brought ahead of the transit and set up on the new forward station. The lamp behind the plumb-target or plumb-line should give a diffused illumination of considerable area so that it may be easily found with the telescope and so that it may render the cross-hairs of the telescope plainly visible. In cases where the illumination of the object is such that the hairs cannot be distinguished, a light is thrown obliquely into the telescope tube in front of the hairs, preferably by a tube reflector (Fig. 133) in front of the object glass.

Sometimes a brass lamp with a small central flame, called a *plummet-lamp*, is suspended in place of a plumb-line and the flame is sighted at, but this is too small a target for quick work and the surveyor may also mistake other lights, such as miner's lamps or candles, for it when sighting through the telescope.

329. Establishing Station Points. — The station point is established either on the floor or on the roof, according to the character and condition of the mine; the chief object sought is permanence of position rather than convenience in getting at the point for future use, which is of secondary importance. The station point, however, should be so placed that it will be possible to set the instrument either over or under it. In a vein mine a timber in the roof, especially a stull, is often more permanent than the floor or rock roof, but any timber is likely to be moved by the miners. The hanging wall is a good place for the station, but if the inclination is small, and the roof liable to cave, as in a coal vein, the foot wall or floor is best.

To establish a station, get a miner to make a drill-hole about six inches deep, more or less, according to the hardness of the

rock. Cut a wooden plug to fit this hole tightly when hammered in dry, and do not let any more of the plug project than is necessary. Small screw eyes make good roof station points from which to suspend the plumb-line, but where the traverse lines are short a finishing nail bent to a sharp angle is better as the plumb-line will then always hang in exactly the same position.

330. Underground Measurements. — For measuring between stations a hundred-foot steel ribbon tape, divided to hundredths of a foot, is used; but for long straight tunnels and shaft work a longer steel wire tape is more convenient. Great care should be taken not to let cars run over the tape as this will invariably snap it. Some mine waters are also very severe on tapes and it is often impossible to keep them dry.

331. Notes of a Mine Traverse. — As a rule the notes of mine surveys are kept in the form of sketches, especially the details, such as the location and extent of the stopes. These details are plotted on to the skeleton survey which is simply a traverse, the notes for which may be kept as shown on pp. 302a-b.

The different station points of this survey are numbered for identification only, their numbers bearing no relation to the distances between them. For convenience the stations on the first level are numbered 101, 102, etc.; on the second level 201, 202, and so on. In larger and more complex mines the system of numbering and lettering stations is carried out still farther.

332. Plotting a Mine Traverse. — This survey can be plotted by computing three sets of coördinates which give all the data needed for showing the mine in plan, longitudinal section, and transverse section. If the three coördinate planes are the meridian plane, the east and west plane, and the horizontal plane, then the vertical and horizontal distances from each slope measurement are first obtained by multiplying the measured distance by the sine and the cosine respectively of their vertical angles. The vertical distance is the difference in elevation between the two points. From the horizontal projection and the azimuth, or bearing, the latitude and departure of the course can be computed as usual (Art. 384, p. 352). A plot of these notes will be seen in Fig. 137.

It is assumed in plotting these notes that all the transit lines

in the galleries run 2 ft. below the roof and in the center of the galleries, which are 6 ft. high and 4 ft. wide; conditions which are more uniform than would occur in actual practice. The measurements which locate the walls of the galleries have been purposely omitted from the foregoing notes for the sake of simplicity.

If it is desired to substitute for the meridian plane a vertical plane through the strike and for the east and west plane one which is at right angles to the strike, then all of the true bearings or azimuths must be corrected by an amount equal to the strike. After these bearings have been corrected the three coördinates are calculated in the same way as described above. The advantage of this latter method is that the levels are shown in their full length in the longitudinal section and the shaft is shown in its true length in the transverse section.

333. UNDERGROUND LEVELING. — The drainage of a mine is usually toward the shaft (Fig. 137), and the grade of the levels is such as will make the tractive force of a full car going towards the shaft equal to the pull required to move an empty car in the opposite direction. When connections, other than vertical ones, have to be made the grades must be taken into consideration. In this work an ordinary surveyor's level is generally used in conjunction with a short leveling rod. Ordinarily this rod is five or six feet long, but may be shorter for use in small coal seams.

334. MINE MAPS AND CHARTS. — The galleries of a mine are often so nearly over one another that confusion is liable to arise in charting, unless some special means of identifying them is employed. As these galleries or working passages appertain to definite levels or strata, a different color may be assigned to each level or stratum and adhered to throughout. The lines of survey are in a colored ink and the passages or workings are of a faint tint of the same color. These colors can also be adhered to on the elevations, of which there are usually two, one along the strike and the other at right angles to it. (See Fig. 137.)

Some surveyors use large-scale plots and simply mark the position of the stations on them, so that when a course has to be set out its distance and direction can be scaled directly from the map.

Another method is to use a small scale map and mark on it, in figures, the exact coördinates of every station point. The origin, or point of reference, is usually the plumb-line of the shaft, and the two vertical planes of reference may conveniently be taken through the estimated general strike and dip of the vein. The true course of the survey lines may also be marked and all the exact data can be clearly kept in a minimum space.

The progress of work in the stopes or rooms of the mine is generally represented on different plans from those used to show the main headings. These working plots may be either vertical, horizontal, or parallel to the vein or seam. In any case, the thickness of the deposit is recorded at frequent intervals together with other particulars, such as thickness of waste or value of ore. (See Fig. 140a.) These thicknesses are all measured at right angles to the plane of the working plan, so that when multiplied by the area on the plot, the cubic capacity of any section is obtained. Where the ore occurs in irregular masses, not conforming particularly to any one plane, the above system does not apply and some other method must be devised by the surveyor.

The best way of estimating amounts not mined is to sketch their probable extent on such a chart from the data available and to make use of the area and thickness method as suggested in the preceding paragraph. Ground explored by boreholes but not opened by headings may be best shown by plotting in plan the positions of both of the walls, where struck in the boreholes, marking the elevations in figures on the plan. Contours may then be sketched in colors, and a very good idea of the shape and trend of the ore body obtained, and the quantities of ore may also be calculated therefrom. (See Computation of Volume, Chapter XII.)

335. LAYING OUT MINING WORK. — Drifts or cross-cuts are laid out by putting in two nails or hooks in the roof, not too near together, from which the miner can hang two plumb-lines and sight the center of the heading he is to run.

Vertical shafts are carefully plumbed on the inside of the frames, and frame by frame, as these are put in. It is best to hang the plumb-line from several frames above the bottom one, as these upper ones are more likely to have ceased to move.

Hang the line an even fraction of an inch each way from the true position of the corners and note any accidental variation in the last frame set, so that in future work, if it is desired to hang the plumb-line from this frame, its error of position can be allowed for. The dimensions of a shaft or drift are given either "in the clear," meaning net measurements inside all timbers, or "over all," meaning gross measurement outside all timber and lagging.

336. UNDERGROUND SURVEYING PROBLEMS. — In the practice of mine surveying, problems are constantly arising which tax the ability and ingenuity of the surveyor, although the actual solution of most of them is quite simple. A few of the common problems met with in such work are given below.

336a. To Find an Ore Shoot by Driving a Level. — The pitch being given by its altitude and azimuth, this serves as a course from any point on the ore shoot whose coördinates are known. The difference in elevation between this point and that of the level to be driven is divided by the sine of the altitude (or vertical angle) of the ore shoot, which gives the slope distance along the ore shoot. The horizontal coördinates of the point where the level will intersect the ore shoot may then be calculated.

FIG. 138.

337. Vertical Angle Correction for Eccentricity of the Top Telescope. — As has been stated in Art. 317, all vertical angles taken by means of the top telescope must be corrected for the eccentricity of this attachment. In Fig. 138 the vertical angle has been taken to a point C in the bottom of a shaft. The distance AC was measured, A being the horizontal axis of the main telescope. Since the transit is set up over a surface station at E, the distances desired are DC and AD. HB and H'A are both horizontal,

$$\text{then } V' = V - ACB = V - v$$

where V is the angle as measured by the top telescope, v is the angular correction for eccentricity, and V' is the corrected angle.

$$\text{Since } \sin v = \frac{AB}{AC} = \frac{\text{Distance between telescopes}}{\text{Distance measured}}$$

we may easily construct a table giving the value of v for any measured distance.

The vertical and horizontal components of AC are then

$$AD = AC \sin V' = AC \sin (V - v)$$

$$\text{and } DC = AC \cos V' = AC \cos (V - v)$$

Had the measured distance been BC instead of AC we should have

$$DC = CF + FD = BC \cos V + AB \sin V$$

$$\text{similarly } AD = BC \sin V - AB \cos V$$

the last term in each equation representing a component of the extra link in the traverse introduced by the eccentricity as explained in Art. 317, p. 289.

The horizontal angle correction for the side telescope is derived by similar reasoning.

337a. Vertical Angle Correction for Eccentric Bearing Telescope. — In Fig. 139, A is the central bearing for the telescope and B is the eccentric bearing in which the telescope rested when the vertical angle V and the distance BC were measured.

$$DC = FC + AB = BC \cos V + AB$$

$$AD = BF = BC \sin V.$$

FIG. 139.

338. To Establish a Boundary Line of the Claim Underground. — In Fig. 140 points A and B are on the boundary of the claim. The shaft is located at S , and it is desired to prolong the underground working in the drift $H'J'$ to a point K' vertically under the boundary line. The surface traverse $BADCS$ is run out,

point S is plumbed down to S' , and the meridian transferred into the mine. Then the underground traverse $S'E'F'G'H'J'$ is run out. The horizontal projections of all the measured lines on both traverses are computed (or measured), and the length

FIG. 140.

of the level line AH' and its bearing can be calculated as described in Art. 398, p. 367. In the horizontal triangle $AH'K'$, AH' and all the angles being known, the line $H'K'$ can readily be computed. If the drift $H'J'$ is not level the distance from H' along the drift to the boundary plane will be equal to the horizontal distance $H'K'$ divided by the cosine of the vertical angle.

339. To Lay Out a Connection in a Mine. — Here the problem is to determine the bearing (or azimuth) and the vertical angle and the distance to run from point A in a mine to point B in another portion of the mine. A traverse can be run from A to B through the passages already cut in the mine, and all the distances reduced to horizontal distances which, together with the azimuths, form a traverse in which the length of the closing line AB (horizontal projection) and its azimuth are missing. These can easily be computed by the method explained in Art. 398, p. 367. The difference in elevation between the actual points A and B together with the length of the horizontal projection of AB will give the vertical angle; from these data the direction and distance between the points A and B can be computed.

340. Plotting Geological Data. — A complete survey should show the boundaries of the various formations, the planes of bedding and the foliation, the fault planes with their displace-

ments, and all veins and dikes encountered. These data could of course be shown to some extent by three coördinate planes as in solid geometry, but it is usually better to plot the geological data taken in each level. Any inclined rock surface is then represented by a series of contour lines corresponding to the levels from which the information is actually obtained. Strikes, dips, and intersections may then be determined by use of a protractor, a scale and a table of cotangents, or a cotangent scale. (See Fig. 140a.)

In a metal mine a plan of each level when filled in with all the geological data will have as much detail as can conveniently be shown. It is usual in such cases to make a geological plan of each level separately on thin tracing paper so that any two or possibly three consecutive ones may be superimposed. The particular position, strike, and dip of any shoot or surface may then be as easily found as though they were all plotted on the same piece of paper.

340a. Location of Ore Shoot Displaced by Fault. — A fault is a displacement along a plane or approximately plane surface. Such a displacement may of course be divided into two direct components and a rotation.

Three distinct measurements have to be made to determine these three variables. A fault wholly in a homogeneous formation supplies none of these measurements. A fault in a foliated formation can in general have only its rotation determined. A fault cutting a homogeneous vein may supply one other measurement but such a vein must have shoots or some other equally distinctive feature in order that all three measurements may be made.

In a general way only one of these measurements appears on the plan of one individual level but two of them may appear by comparison on the plans of two levels by the tracing paper method previously mentioned and all three may be shown by a similar comparison of three levels. The components of displacement need not be always determined in order to plan for future excavations. It will in general be sufficient to use a scale and a straight-edge to determine the position of an ore shoot on the next level to be opened up. Fig. 140a shows how these components may be

determined and made use of, however, in cases of necessity. The left portion of the figure shows a plan of a vein the two parts of which have been separated by a fault. The directions of the horizontal lines marked "mean course of vein" and of the horizontal lines on the fault planes have been determined at each level in the mine. The line AB represents the horizontal distance between the two portions of the vein, measured along the fault plane, and its length may be scaled directly from the plan. The dips of the vein and of the fault plane are indicated by arrows. The distances CD , EF , and GH , when scaled off with the cotangent scale, will give the angle of dip of the vein, fault, and ore shoot respectively, since these distances are taken between points which differ just 100 feet in elevation. The vertical distance between the two portions of the vein may be measured by scaling JK with the vertical scale shown at the left of the figure. The "feet" on this scale are not shown their true length but are reduced in the ratio of $1 : \cot(\text{dip of vein})$, i.e., if a right triangle were constructed having 1 foot as its vertical side and one of these scale units as its horizontal side the hypotenuse would have the same slope as the vein. This scale cannot be used, of course, in any other direction than perpendicular to the strike of the vein.

On the right of the figure are shown a view looking perpendicular to the plane of the vein and one perpendicular to the fault plane. The former shows the method of recording the quantities of ore removed and the results of assays. The latter shows the actual *displacement*, the point L having been at M before the faulting took place.

Where only one level is opened up the dips of faults and veins must be determined as accurately as the short distance between roof and floor affords. This determination can only be approximate as local irregularities of strike and dip are very numerous. Where there are several consecutive beds which have been explored either by headings or boreholes it is best to represent each bed by contours on a separate plan; these can be plotted on tracing paper if it is necessary to examine the relations of consecutive beds to one another or to the surface. Fault planes cutting folded beds will show as curved lines but can be readily plotted or examined as to strike, dip, and displacement from the plan of only one

curved or folded bed, by the aid of a section on the plane of the fault which can be plotted from the data on this plan.

341. HYDRAULIC SURVEYING FOR MINES. — The miner's unit for measuring water is the *miner's inch*. By an inch of water was originally meant such continuous flow as will go through a one inch square hole, the head of water behind it being usually six to nine inches. This very loose definition has been done away with but the name still applies, being defined more exactly as ninety cubic feet of water per hour ($1\frac{1}{2}$ cubic feet per minute). In spite of all criticism, the miner's inch has become by custom the standard unit for the flow of water in most mining districts. It no doubt retains its hold on the practical mind because no good definite time or capacity units are in general use, seconds, minutes, hours, and days, or gallons and cubic feet with their clumsy relations to one another, being used according to the whim of the individual. To get an idea of the magnitude of a standard miner's inch, it may be remembered that it is equivalent to a stream one inch square running at a uniform rate of 3.6 feet per second. This is about a medium speed for small mountain streams; and, with a little practice, the flow of such a stream in miner's inches may be calculated mentally, after rough measurements have been made of the cross-section of the stream and the speed of flow of the water at the surface. The accuracy of this process is within the ordinary limits of fluctuation of the stream from day to day. If the flow has to be recorded over a long period it is well to put in a *weir*.

For estimating the flow of larger and more important mountain streams, a portion of the stream where the width and flow are comparatively uniform may be chosen and the length of this portion measured and marked by flags. A cross-section of the bottom of the stream is obtained at each flag and at intermediate points if necessary by measuring the depth at equal intervals across the stream; from these a mean cross-section is obtained. Floats are started at intervals across the stream opposite the up-stream flag, and timed with a stop watch while running to the down-stream flag; the speed of each float represents the velocity of the stream in its respective longitudinal strip. Each velocity is multiplied by the area of the corresponding portion of the

cross-section of the stream, and from the total flow so computed a certain percentage is deducted for the excess of surface over mean flow; this, for ordinary mountain streams, is roughly twice the percentage of the grade of the channel. For details regarding stream measurements, see Chapter IX of Volume II.

The surveying and staking out of mining ditches, flumes, and pipe lines follow the general practice for this work in other fields of engineering.

342. Testing for Ore by Electric Currents. — Methods of testing the earth for ores by means of electrical currents and waves are being experimented upon, and the working out, recording, and plotting of the results are likely to become a part of the mine surveyor's work.

SURFACE SURVEYING.

343. SURFACE SURVEYING IN RUGGED MOUNTAIN REGIONS.

— In accurate work, such as the surveying of mining claims for patent,* the ordinary mining transit may be used. Measurements are made with a steel wire tape, 300 to 500 feet long and marked every 10 feet (or 20 feet) so as to be used with a short auxiliary steel ribbon tape which is divided to hundredths of a foot. The measurements are taken from the center of the instrument to the object at which it is pointed, care being taken not to overstretch the tape nor to kink it. The most accurate work is done by stretching the tape with a tension handle (a spring balance) which can be attached by a clamp to any part of the tape. Where it is feasible, just enough tension is given so that the stretch of the tape compensates for the shortage due to sag. In many cases assistants will have to hold the middle point or the points at one-third and two-thirds the length of the tape up to the line of sight, giving at the same time enough pull to make the sag equal in the different sections of the tape.

There are several systems of traversing. The most common is to measure the height of the center of the instrument above the

* By patent proceedings is meant the proceedings necessary to obtain from the government a fee simple deed to the mining claim.

station point, and then to sight an equal height on a graduated staff held on the back and forward stations, recording the azimuth, vertical angle, and distance. Another method is to sight and measure to targets set at a fixed height above the stations, recording the vertical angle only at alternate stations. If the vertical angles are read at every station there will be two sets of vertical angle and distance measurements. The three tripod method may also be used as described for underground work; and lastly two transits and instrument-men may be employed, each sighting to the other's telescope and measuring the distances between them. Each of these methods has its advantages and disadvantages, and the best one to use depends upon the conditions of the work to be done. In some cases there will be twice as many vertical angles and in some cases twice as many distance readings as are actually needed, but these extra readings may be used as a check available in the field.

In making general maps of a mining district, only monuments and important locations need be accurately shown. This accurate work which is the first to be done forms a skeleton on which to make a general map. The topography can be filled in by a transit fitted with fixed stadia wires and a compass.

The best topographical data in mountainous country are obtained by running traverses along the ridges and valleys; these are also usually the best places to travel. Much sketching is necessary and the work should be plotted by the surveyor himself each day as the work proceeds. In this work a rough determination of the topography is sufficient, since the plans are usually plotted to the scale of $\frac{1}{10000}$ or smaller, and therefore such instruments as the hand compass, clinometer, and aneroid barometer can be used. With such instruments one man can do the entire work. The plane table cannot be used to advantage in mountain or mine surveying, but photographic surveying may often prove useful in filling in details of topography.

344. MINE BOUNDARIES.—APPROPRIATIONS UNDER UNITED STATES LAWS.*—In most countries mineral rights are defined

* For further information with regard to this subject see the Manual of Instructions for the Survey of the Mineral Land of the United States, issued by the Commissioner of the General Land Office, Washington, D. C.

by vertical planes through lines marked out on the surface. Title to metalliferous lands, however, as granted by the United States, conveys the right to all minerals included in the downward prolongation of the portions of veins cut off by the vertical end bounding planes, i.e., a vein can be worked in the dip indefinitely, but in the direction of the strike it is limited by the end bounding planes of the claim. This law has given rise to much litigation and there are still many unsettled points involved.

The Federal law allows a claim to cover 1500 feet located along the direction of a vein and 300 feet of surface ground on each side of it. These dimensions which constitute the maximum can be reduced by local laws. The ordinary method of locating a claim is shown in Fig. 141. The discovery being

FIG. 141. PLAN OF LODGE CLAIM.

made at *D* the center line *WC-D-EC* is run and then the end lines *SE-NE* and *SW-NW* are put in, being made parallel with each other and straight. The side lines need not of necessity be parallel and are not usually run out on the ground.

A monument with explanations is placed at each of the seven points marked. If in a timbered country, the lines run should be blazed, and squared trees may be used as monuments. At *D* (Fig. 141) a location notice is posted, defining the boundaries of the claim and containing such explanation as would identify the claims in case of dispute. The miner usually makes the location survey himself, using approximate courses and distances. There is legally no objection to this work being done roughly, but when a patent survey comes to be made, neither the dimensions specified in the location notice nor the limits of the claim as marked off on the ground can be exceeded. So when the location survey is roughly made certain "fractions" of ground

are not included, and these may cause much trouble, especially when "groups" of claims are located.

In such preliminary surveying, traverses may be run along courses where the sights can be conveniently taken; this may save much time and considerably simplify the work, especially in thickly timbered regions (Art. 329, p. 302). In the description it is sufficient to state the approximate compass bearings of the boundaries. The center line and side lines need not be straight or parallel, but are assumed to be so unless marked with additional monuments. If, on account of the crookedness of the vein, it is advisable to make the center line of the claim a series of straight lines (like a traverse), this can be done, but the above conditions must be fulfilled with regard to the length and breadth of the claim and the two end lines must be parallel. In order to guard against troublesome litigation, an effort is sometimes made to surround a valuable claim with others, thus forming a "group." The more valuable claim is then protected as regards all "extra-lateral rights."

Flat deposits, such as coal and placer, are subject only to vertical bounding planes, and, provided the boundaries are approximately north and south lines, marked plainly on the ground, and the legal area is not exceeded, no difficulty need be encountered. The Federal law allows 20 acres to be taken for a placer claim but fixes no limits in regard to breadth or length. Local or state laws can regulate the size, provided the 20 acre limit per claim is not exceeded. The coal lands law is made subject to the general system of public land surveys for agricultural lands. (See Chapter V.)

345. SURVEYING FOR PATENT. — The surveying of claims for patent from the United States Government can only be obtained by those who have received appointment of United States Deputy Mineral Surveyor and they must have an order from the Surveyor General of the state or territory in which the claims are located before making any such survey.

In surveying for patent, much more accurate work has to be done than when merely locating a claim. After the shape of the claim as originally staked has been determined, the positions of the new corners and other boundary marks are computed and

laid out on the ground. The original claim cannot anywhere be exceeded and usually has to be cut down so as to make the end lines parallel and bring the dimensions of the claim within statutory limits. All this must be done accurately, the limit of error allowed being one in two thousand. Besides the marking of the boundaries on the ground, the position of at least one of the corners of each claim must be determined with reference to permanent monuments recognized by the government. The true meridian must also be determined by observations of the sun and all courses must be referred to it. The position of all buildings and surface improvement must be found and shown on the plot, and also the position of all corners of other claims for which a patent has already been applied. The surveyor must also make an estimate of the value of and describe all improvements, such as tunnels, shafts, open-cuts and other mining work done on the ground, and these should amount to not less than \$500.00 worth per claim. The Manual of Instructions describes a great many other details which must be known to the Deputy Mineral Surveyor before his survey will be accepted, and defines the penalties attached to poor or dishonest work. Patented claims may overlap, and in fact do, in all mining districts, but in making application for patents to claims which lap on ground previously patented, the exact rights desired on the area of intersection must be defined.

Placer claims may be taken in twenty acre tracts, the bounding lines of which must conform with the general system of survey lines established by the Government, but if such survey has not been extended to the district, they must be bounded by true meridian and east and west lines. The survey of coal land is subject to somewhat similar rules.

346. THE SURVEYING OF BOREHOLES. — Boreholes, whether made by a rotary or a percussion drill, are never perfectly straight and unless the ground is remarkably homogeneous, are not amenable to any mathematical law. Means have been devised, however, of measuring the strike and dip of a hole at any particular distance from its mouth. The trend of the borehole can thus be plotted with some degree of approximation and the position of any particular body or stratum struck

in the borehole determined. One method depends in principle upon the conversion from liquid into jelly, by cooling, of a solution of gelatin, contained in a small vessel together with a compass needle and a plumb-bob and of such a shape as to align itself with any part of the hole in which it may be placed.

Another instrument takes a photographic record of the position of the compass needle and plumb-bob, after the lapse of such an interval of time as is necessary to place the instrument in proper position and allow the needle and plumb-bob to come to rest. The position of points in any plane stratum, as found by three boreholes, determines it. If, however, the angle at which a borehole cuts this stratum is known, only two boreholes are necessary and if the strike and dip of the stratum is known, one borehole is sufficient to determine it.

347. STAKING OUT THE PROBABLE APEX OF A VEIN. —

It is often required to prolong the course of an inclined vein on the rugged surface, either for exploration purposes or to locate a claim. This may be accomplished by setting up on the vein a transit fitted with a solar attachment, the main telescope being inclined at the angle of dip of the vein in altitude and pointed at right angles to the strike in azimuth. The solar attachment, when set for the zero declination, will sight points only in the plane of the vein.

As veins are usually somewhat irregular, the survey need not necessarily be made with a transit. Instead, a small plane table may be improvised so that all points in the plane of the deposit can be conveniently sighted, the plane table having been brought into the plane of the vein.

348. ECONOMIC PRINCIPLES. — The surveying of mine workings is strictly an economic problem and the surveyor must study it as such. The accuracy attained must be such that the cost in obtaining it and the saving of expense in mining operations through it together effect the maximum of economy. The surveyor bearing this in mind will be neither too careless nor too exact. He will not, for example, close down the mine in order to carry a meridian into it when no important connections are needed, and there are no boundary disputes. On the other hand, in some cases accuracy of a survey is of such prime impor-

tance that a temporary interference with the working of the mine may be warranted.

In any given case the surveyor must make a scientific measure of the accuracy required. There is no better method of obtaining results of known accuracy than to go over the lines several times with varying conditions, but this is not always good economy, especially in such work as plumbing a shaft which necessitates a temporary stoppage of all hoisting operations. Often the controlling error will be due to the plumbing of the meridian. In Fig. 142, D is the horizontal distance in a straight line from the shaft to the connection, d is the distance between the plumb-lines, and e its error as ascertained by measuring or other means.

FIG. 142.

The controlling error at the connection is $E = e \frac{D}{d}$ and is in a direction perpendicular to that in which D was measured on the chart. This is obvious, for the surveys of the galleries are considered accurate, the error being one of relative rotation around the shaft as an axis. Where there are many angular errors of the same degree of magnitude, such as occur when a number of short sights are included in the traverse, the distances may be measured from these short lines to the connection and their respective errors E_1, E_2, E_3 , etc. found at these localities. These are then resolved according to their respective latitudes and departures into S_1, S_2, S_3 , etc., and W_1, W_2, W_3 , etc. The greatest

possible error is then $S_1 + S_2 + S_3 + \text{etc.}$ to the north or south and $W_1 + W_2 + W_3 + \text{etc.}$ to the east or west, these summations being made without regard to any sign.

Likewise the mean probable error is $\sqrt{S_1^2 + S_2^2 + S_3^2 + \text{etc.}}$ to the north or south and $\sqrt{W_1^2 + W_2^2 + W_3^2 + \text{etc.}}$ to the east or west. Errors due to the measurement of distances are not likely to be great, but if necessary these may be divided into latitudes and departures directly and compounded with those due to angular error.

Besides being of immediate service to the surveyor, the practice of computing possible and probable errors gets him in the habit of thinking along the most business-like lines instead of drifting into a rut or losing interest in his work.

The surveyor should keep his plans up to date and see that the men in charge of the mining operations fully understand their instructions; for many mining men of considerable experience get entirely wrong notions of the shape of their workings and are often too proud to ask for information. The surveyor, without assuming a "know-it-all" attitude, can, from the specialized nature of his work, often make useful suggestions in regard to the exploration of a mine. By working always in harmony with the other officials of the mine, he can further the interests of all concerned, both employers and employees.

PROBLEMS.

- ✓ 1. From a monument at the mouth of a tunnel a line is run in the tunnel, azimuth $37^\circ 24'$, slope distance 424 ft., vertical angle $+ 2^\circ 10'$; thence azimuth $62^\circ 42'$, slope distance 278.5 ft., vertical angle $+ 2^\circ 18'$ to breast. From the same monument a line is run on the surface, azimuth $98^\circ 33'$, slope distance 318.5 ft., vertical angle $- 3^\circ 22'$; thence azimuth $38^\circ 02'$, slope distance 647 ft., vertical angle $+ 14^\circ 13'$ to the center of a vertical shaft. How deep must the shaft be to meet a connecting drift run on a grade of $+ 2.4\%$ from the breast of tunnel, and what is the slope length and azimuth of this drift?
- ✓ 2. The strike of a certain vein at point of outcrop is $N 43^\circ E$ and the dip is $71^\circ 50'$, pitch S.E. From this point of outcrop a surface line is run, $N 83^\circ 15' E$, slope distance 248 ft., vertical angle $- 12^\circ 34'$; thence $S 2^\circ 54' E$, slope distance 208.5, vertical angle $- 14^\circ 34'$ to a point from which the tunnel is to be driven in the direction $N 71^\circ W$ and with a grade of $+ 3.8\%$ until it intersects the vein.

- (a) What would be the slope length of such a tunnel?
- (b) What would be the slope length and bearing of the shortest possible tunnel run on a $+1.3\%$ grade to intersect the vein?
- ✓ 3. A vein has a strike of $S\ 67^\circ\ W$ and its dip is 55° . What is the azimuth of an incline on the vein having a slope of 44° ?
- ✓ 4. From the bottom of vertical shaft No. 1 a horizontal traverse was run in the mine to the bottom of vertical shaft No. 2 as follows: Assumed azimuth 0° , distance 243 ft.; thence azimuth 340° , distance 121 ft.; thence southeasterly a distance of 473 ft. along a vein which shows a strike of 60° (azimuth) and a dip of 35° ; thence azimuth 42° , distance 25 ft. to the center of shaft No. 2. From a point vertically above the last point a line is run on the surface with true azimuth $116^\circ\ 20'$, distance 411 ft. (horizontal) to a point A from which the center of shaft No. 1 is sighted at azimuth $71^\circ\ 30'$.
- (a) How much deeper will shaft No. 2 have to be sunk to reach the vein?
- (b) What is the true strike of the vein?
- ✓ 5. A vertical winze has been sunk below the level of a tunnel. It is desired to sink a vertical shaft from the surface to connect with the winze. The monument X is established at the mouth of the tunnel and the monument Y is near the site of the proposed shaft. Y bears $S\ 88^\circ\ 58'\ 56''\ W$, 896.796 ft. from X . The following are the notes of the survey connecting X and the winze corners A , B , C , and D :—

Station.	Mean Deflection.	Horizontal Distance.	Station.
X	$0^\circ\ 00'$	896.796	Y
Y	$45^\circ\ 05'\ 34''\ R$	403.080	1
1	$74^\circ\ 05'\ 06''\ L$	587.208	2
2	$32^\circ\ 23'\ 43''\ L$	67.000	3
3	$54^\circ\ 43'\ 47''\ R$	44.803	4
4	$39^\circ\ 51'\ 57''\ R$	41.075	5
5	$31^\circ\ 10'\ 10''\ R$	19.573	Cor. A
	$31^\circ\ 10'\ 10''\ R$	27.240	Cor. B
	$31^\circ\ 43'\ 40''\ R$	21.477	Cor. C
	$24^\circ\ 02'\ 40''\ R$	25.773	Cor. D

Required the location of the shaft corners on the surface.

6. From a monument M at the mouth of a tunnel a traverse is run in the tunnel, azimuth $20^\circ\ 35'$, distance 352 ft., vertical angle $+1^\circ$ to point A ; thence azimuth 61° , distance 528 ft., vertical angle $+0^\circ\ 40'$ to point B at the breast of the tunnel. From M a surface traverse is run, azimuth $25^\circ\ 10'$, distance 578 ft., vertical angle $+4^\circ\ 25'$ to point C ; thence azimuth 11° , distance 407 ft., vertical angle $+14^\circ\ 20'$ to point D , which is the center of a vertical shaft 120 ft. deep. Find the length and grade of a connecting incline from the bottom of the shaft to the breast of the tunnel.

7. Assuming the transit to be in perfect adjustment what is the error in horizontal angle in sighting down a 500-ft. shaft, 5 ft. in breadth, when the telescope cannot be sighted closer than 3 seconds along the inclined line?

PART III.
COMPUTATIONS.

PART III.

COMPUTATIONS.

CHAPTER XII.

GENERAL PRINCIPLES.—MISCELLANEOUS PROBLEMS.— EARTHWORK COMPUTATIONS.

349. GENERAL REMARKS. — The ultimate purpose of many surveys is to obtain certain numerical results to represent quantities such as areas or volumes. In the section on Surveying Methods it has been pointed out that in all surveys there should be a proper relation between the precision of measurement of the angles and distances. To secure final results to any given degree of precision, the measurements in the field must be taken with sufficient precision to yield such results. In computing from a given set of field notes the surveyor should first determine how many places of figures he should use in the computations, the aim being to obtain all the accuracy which the field measurements will yield without wasting time by using more significant figures than are necessary. Professor Silas W. Holman* in the preface to his "Computation Rules and Logarithms" says:—"It would probably be within safe limits to assert that one-half of the time expended in computations is wasted through the use of an excessive number of places of figures, and through failure to employ logarithms."

Final results should be carried to as many significant figures as the data will warrant and no more. In order to insure the desired precision in the last figure of the result it will usually be necessary to carry the intermediate work one place further than is required for the final result.

350. The number of significant figures in the result of an observation is the number of digits which are known. For instance, if a distance is recorded as 24,000 ft. when its value was

* See "Computation Rules and Logarithms," by Professor Silas W. Holman, published by Macmillan & Co., New York.

obtained to the nearest thousand feet only, it contains but two significant figures. The zeros are simply put in to show the place of the decimal point. If, however, the distance has been measured to the nearest foot and found to be 24,000 ft. there are five significant figures, for the zeros are here as significant as the 2 or 4. Similarly a measurement such as 0.00047 contains but two significant figures, the zeros simply designating the position of the decimal point, for, had this same value been recorded in a unit $\frac{1}{100,000}$ as large the result would have been 47.

Again, if a series of rod-readings are taken on different points to thousandths of a foot and three of the readings are 4.876, 5.106, and 4.000 it is evident that each of these readings contains four significant figures; if each of them is multiplied by 1.246 the respective results are 6.075, 6.362, and 4.984. But had the results been measured to the nearest tenth of a foot and found to be 4.9, 5.1, and 4.0 these values when multiplied by 1.246 should appear as 6.1, 6.4, and 5.0. This illustration indicates the proper use of significant figures. Since the rod-readings 4.9, 5.1, and 4.0 are reliable only to about 1.5 to 2 per cent. the multiple 1.246 should be used in this computation as 1.25. Similarly in the use of such a constant as $\pi = 3.1415927$ it is a waste of time to use any more significant figures in the constant than exist in numbers with which the constant is to be combined in the computation.

351. In deciding how many places of decimals to use in the trigonometric functions the student should examine the tabular differences and determine what percentage error is introduced by any error in an angle. For example, suppose an angle of a triangle to have been measured in the field to the nearest minute. There may be an error of 30 seconds in this angle, and it will be seen from the table of natural sines that the tabular difference for one minute in the fourth decimal place varies from 3 for a small angle to less than 1 for a large angle, and that the variation is about the same for cosines, and for tangents and cotangents of angles under 45° . Then for half a minute the difference will be, on an average, about 1 in the fourth place. Therefore, in general, four places will be sufficient when the angles have been measured to the nearest minute only. But if there are several steps in the computations it may be advisable to use

five-place tables. Similarly it can be seen that five-place tables of functions will, in general, give angles to the nearest 10 seconds, and six-place tables to the nearest second. These are only average results and are intended to give the student a suggestion as to how to decide for himself whether to use four, five, or six-place tables. It is obviously a great saving of time to use four-place tables where four places are needed rather than to use six or seven-place tables and drop off the last two or three digits. The amount of labor increases about as the square of the number of places in the tables, i.e., work with 6-place tables: work with 4-place table = $36:16$.

352. The following simple examples illustrate the uselessness of measuring the distances with a precision which is inconsistent with that of the angles, when the angles are to be used in the computation of other distances. Given the measurements shown on Fig. 143. If the angle B was measured to the nearest minute only there may be an error of 30 seconds in this angle and the tabular difference for 30 seconds for the sine and cosine of this angle in four-place tables is 0.0001; therefore use four-place tables. In this case it is evident that the 0.02 on the hypotenuse distance is of no value whatever in determining the length of the other two sides a and b , that the 0.6 being the fourth significant figure should be retained, and that the resulting length of a or b will not be reliable to more than four significant figures.

FIG. 143.

$\log 773.6 = 2.8885$	$\log 773.6 = 2.8885$
$\log \cos 44^\circ 12' = 9.8555$	$\log \sin 44^\circ 12' = 9.8433$
$\log a = 2.7440$	$\log b = 2.7318$
$a = 554.6$	$b = 539.3$

If it is assumed, however, that the angle B is measured by repetition and found to be $44^\circ 12' 25''$ the error in the original angle then was about $25''$. By using the same value for the hypo-

tenuse (773.6) and six-place tables to secure greater precision the value of a is 554.5 and of b 539.4. Comparing these results with those obtained above will give a good idea of the error in length of these lines due to reading the angle to the nearest minute only and also a proper conception of the fallacy of computing with tables of more than four places when the angles are read to the nearest minute only. The difference between the values of a and b obtained by use of the angle $44^\circ 12'$ and similar results by use of $44^\circ 12' 25''$ is due entirely to the $25''$ and not to the fact that four-place tables were used in the former case and six-place tables in the latter, for in both cases the result has been obtained to four significant figures only.

It is also evident that when the angle B was measured to the nearest minute it was inconsistent to measure the hypotenuse closer than to the nearest tenth of a foot. But if angle B was measured to the nearest 10 seconds the line AB should have been measured to the nearest hundredth. It should not, however, be assumed that in all cases where angles are only measured to the nearest minute the sides should be recorded to tenths of a foot. It is the **percentage** error in the measurement of the sides which must be the same as the **percentage** error in the angles. If the sides are very short, they should be measured to hundredths of a foot to be consistent with angles to the nearest minute. In general, when the angles are read to nearest minute only, the sides should be measured to four significant figures; with angle to nearest 10 seconds they should be measured to five significant figures; and with angles measured to 1 second the sides should be measured to six significant figures. All the sides of a triangle of considerable size might be measured to hundredths of a foot, the angles being recorded to the nearest minute only, and the distances used for the computations, the angles serving merely as checks; this, of course, is practicable at times.

353. In Fig. 144 the angle is measured to the nearest minute,

FIG. 144.

but the distance is measured to hundredths of a foot. In this case we are to determine the length of a long line from a short one and the error in the short line is therefore multi-

plied several times. The same degree of precision should be secured in the measured line BC as is desired in the computed lines AC or AB , which, it is assumed in this case, is required to four significant figures. In order that the measurements of line BC and angle A may be consistent with the precision of the required result, BC should be taken to the nearest hundredth of a foot and angle A to the nearest minute. In this computation four-place tables should be used and the value obtained for AC or AB should be recorded only to four significant figures.

$$\begin{aligned}\log 12.34 &= 1.0913 \\ \log \tan 3^{\circ}56' &= \underline{8.8373} \\ \log AC &= 2.2540 \\ AC &= 179.5\end{aligned}$$

If AC is desired to the nearest hundredth of a foot the angle A might be determined closely by repetition, but this will not give the length AC to the nearest hundredth unless BC has been measured closer than to the nearest hundredth; for, suppose there is an error of 0.005 ft. in the measurement of BC , then the line AC being about 15 times as long as BC will have an error of 0.075 ft. no matter how exact the angle at A may be measured. In other words, if AC is desired correct to five significant figures BC should contain five significant figures. Evidently the practical way of obtaining an exact value for the inaccessible distance AC is to measure AB to the nearest hundredth, and to compute AC from AB and BC , using the angle at A as a check on the measured distances. In both of the above examples it is assumed that the 90° is exact.

354. LOGARITHMIC OR NATURAL FUNCTIONS.—The question as to whether logarithmic or natural functions shall be used will depend upon the computation in hand. Many surveyors have become so accustomed to using naturals that they will often use them when logarithms would require less work and offer fewer opportunities for mistakes. Each method has its proper place, and the computer must decide which will be the better in any given case. The use of logarithms saves considerable time spent in actual computation because the process is

simpler, but, on the other hand, looking up the logarithms consumes time. The result is in many cases, however, a saving of time over that required to do the arithmetical work of multiplying or dividing. While the multiplication of two numbers of three or four digits each can possibly be done directly more quickly than by logarithms, still it takes more mental effort and there is more opportunity for making mistakes; but in case several such multiplications are to be made logarithms are almost always preferable. Furthermore when there are several multiplications of the same number logarithms will save time since the logarithm of this common number has to be taken from the table but once. Frequently, however, the computation is so simple that the use of logarithms would be almost absurd, e.g., the multiplication of any number by a simple number like 20, 25, 150, or 500. If a function of an angle is to be multiplied or divided by

any such number the natural function should of course be used.

$$\text{Vers } A = \frac{CD}{AB}$$

$$\text{Exsec } A = \frac{EB}{AC}$$

FIG. 145.

355. SHORT CUTS.—The solution of a right triangle, when one of the angles is small, involving the use of the cosine of this small angle, can often be more easily obtained by the use of the versed sine or external secant of the angle. In Fig. 145

$$AB = 207.42$$

$$A = 7^\circ 32'$$

$$AC = 207.42 \cos 7^\circ 32' \quad (1)$$

$$\text{But } AC = AB - CD$$

$$= 207.42 - 207.42 \text{ vers } 7^\circ 32' \quad (2)$$

$$= 207.42 - 207.42 \times 0.00863$$

$$(207.42 \times 0.00863 = 1.79, \text{ by slide rule.})$$

$$= 207.42 - 1.79$$

$$= 205.63$$

Obviously, when the angle is quite small, the result of the multiplication indicated in (2) can be taken from the table to the nearest hundredth of a foot with much less effort than is required for the computation called for in (1). In fact, the computation in (2) can often be done more quickly by the use of natural numbers than by logarithms, and in most cases the slide rule will give results sufficiently exact (Art. 359, p. 330).

Had AC been given (205.63) and the angle A , ($7^\circ 32'$) then

$$AB = \frac{205.63}{\cos 7^\circ 32'}$$

$$\text{But } AB = AE + EB$$

$$= 205.63 + 205.63 \text{ exsec } 7^\circ 32'$$

$$= 205.63 + 205.63 \times 0.00871$$

$$(205.63 \times 0.00871 = 1.79, \text{ by slide rule.})$$

$$= 205.63 + 1.79$$

$$= 207.42$$

356. There are many "short cuts" in arithmetical work which are of great value to the computer, and the student should endeavor to learn the most common and simple ones. The following are a few illustrations.

$$247 \times 25 = \frac{247 \times 100}{4} = \frac{24700}{4}$$

$$682 \times 50 = \frac{68200}{2}$$

$$694 \times 150 = 69400 + 34700$$

$$927 \times 62.5 = 92700 \times \frac{5}{8}$$

$$672 \times 1002.3 = 672000 + 1344 + 201.6$$

$$547 \times .9968 = 547 (1 - .0032) = 547 - 5.47 \times .32$$

$$\frac{43}{60} = \frac{4.3}{6} \text{ (reducing minutes to decimals of a degree)}$$

$$\frac{843}{12.5} = 8.43 \times 8$$

The student should cultivate the habit of performing mentally as much of the work as can be done without fatigue, delay, or danger of mistakes. No hard and fast rule can be laid down in this matter, as some persons have more aptitude than others for work of this kind. Such subtractions as $180^{\circ}-36^{\circ}47'18''$ should always be performed mentally. Also in taking the logarithm of a number from a table of logarithms the result should be written down directly.

357. ARRANGEMENT OF COMPUTATIONS.—All surveying computations should be kept in a special computation book. At the head of the page should appear the title of the work, the number and page of the field note-book from which the data are copied, the names of the computer and checker, and the date. The work should be arranged neatly and systematically so that every part of the computations can be traced by any one who is familiar with such work. Where possible the work should be so arranged that numbers will have to be written but once. Each important value, each column, etc. should be labeled so that it can be readily found.

358. CHECKS.—It is very important that all calculations should be checked, not merely at the end of the computation but also at as many intermediate steps as possible. In this way a great waste of time may be prevented and serious mistakes avoided. One good method of checking is to perform the operations when possible by two independent methods, for example, by the use of logarithms and by natural functions. Very often two men do the computing, one man's work acting as a check on that of the other. The two may each work by the same or by different methods, and the results may be compared at intervals. **Every part of the work should be done independently, from the copying of data out of the note-book to the final results.** It is not uncommon to find two men computing the same area where only one of them looks up the logarithms. In case a mistake is made in looking up the logarithms the results may check but both are wrong. The computer should also check his work roughly by estimating approximately what the result should be.

359. SLIDE RULE.—A valuable aid in checking calculations is an instrument known as the *slide rule*, which enables the computer

to multiply and divide numbers by logarithms by a purely mechanical process. It is really the equivalent of a table of logarithms. It consists of a wooden rule, usually about 10 inches long, having a groove in one side in which runs a small wooden strip called the slide. On one face of the rule are placed two scales, *A* and *D*, Fig. 146, one above and one below the slide which is indicated by

FIG. 146.

B and *C*. These are constructed by plotting logarithms of numbers by subdividing a unit of some convenient length, say 10 inches. For example, the log of 1 is 0, so this is taken as the left end of the scale and the number 1 placed at this point. The log of 2, to three significant figures, is 0.301, and a line is placed therefore at a distance equal to $\frac{301}{1000}$ of the 10 inches, or 3.01 inches, and marked with the number 2. Similarly at 4.77 (log 3 = 0.477) a line is marked 3. In this way the logarithms of other numbers are plotted. The space between 1 and 2 is subdivided by plotting log 1.1, log 1.2, etc. The subdivision is continued until the spaces are as small as will admit of rapid and accurate reading of the scale.

It is customary to make the spacing on the upper scale just half that on the lower, i.e., if 10 inches is chosen as the unit for the lower scale, then the unit for the upper scale will be 5 inches. Since the length of this upper scale is only half the length of the rule there are usually two scales exactly alike marked on the upper part of the rule, the right end of one coinciding with the left end of the other.

On the slide are two scales, *B* and *C*, exact duplicates of those on the rule and so placed that when the end line of the scale *B* on the slide is placed opposite the end line of the scale *A* on the rule, every line on the slide is exactly opposite its corresponding line on the rule. A *runner* is usually attached to the rule for convenience in setting and reading the scales. This runner is a small metal slide which fits over the face of the rule in such

a way that it can be slid along the rule and set at any reading of the scale. It is usually provided with a fine line running cross-wise of the rule which is used in marking the exact setting.

Multiplication or division of numbers is performed by adding or subtracting the scale distances corresponding to these numbers. The scale distance is the logarithm of the number. Adding two scale distances is, in effect, adding two logarithms, and the resulting scale distance is the logarithm of the number marked opposite on the scale. For example, if the left end of scale *C*, Fig. 147, is set opposite the number 2 of the scale *D*, then opposite the number 3 on scale *C*, is found the product, 6, on scale *D*. The distances which have been added are those corresponding to $\log 2$ and $\log 3$ respectively. The sum of these distances is the distance corresponding to $\log 6$. Division is performed by placing the divisor on scale *C* over the dividend on scale *D* and reading the result, opposite the end of the scale *C* on the scale *D*.

Fig. 147 shows the position of the scales for dividing 6 by 3.

FIG. 147.

The scales *A* and *B* may be used in a like manner. It is evident that, by setting the runner on the result of one operation and then moving the slide so that one of its ends coincides with the runner setting, continued multiplication and division can be performed without the necessity of reading intermediate results.

Scale *D* may be used in connection with scale *A* for obtaining squares or extracting square roots. Since the spaces on scale *A* are one-half those on scale *D* the number 4 on scale *A* is opposite number 2 on scale *D*, 9 is opposite 3, and so on, every number on scale *A* being the square of the corresponding number on scale *D*. Other scales, generally log sines and log tangents, are placed on the reverse side of the slide, so that trigonometric calculations can also be performed with this instrument. Results

obtained with the ordinary 10 inch slide rule are usually correct to 3 significant figures, so that this slide rule is the equivalent of three-place logarithm tables.

360. Thatcher Slide Rule. — The Thatcher slide rule consists of a cylinder about four inches in diameter and eighteen inches long working within a framework of triangular bars. On these bars is fastened a scale corresponding to the scale on an ordinary slide rule, and on the cylinder is marked another scale like that on the bars. The cylinder is the *slide* and the triangular bars form the *rule*. This rule is operated in a manner similar to the one explained above. Results can be obtained with it which are correct to four and usually to five significant figures.

361. REDUCING THE FIELD NOTES FOR COMPUTATIONS. — Before any of the computations are made the measurements taken in the field frequently have to be corrected on account of erroneous length of tape. This correction can usually be made mentally when the distances are transcribed into the computation book. The errors in the angles are balanced by altering the value of those angles which were taken from short sights since the angular errors are most likely to occur in these. In some cases, where it has been found desirable to take measurements on a slope, these distances are reduced to horizontal distances by multiplying them by the versed sine of the vertical angle and subtracting the result from the *corrected* slope distance; the correction for error in the tape being made *before* this is done. Sometimes instead of a vertical angle the slope distance and the difference in elevation between the points are the data contained in the field notes. In this case the formula given in Art. 20, p. 13, should ordinarily be used.

362. CURVED BOUNDARY BY OFFSETS. — The offsets to the brook (Fig. 53, p. 104) were taken at regular intervals in one portion of the survey and in another portion offsets were taken at the points where the direction of the brook changes. The offsets which were taken at regular intervals give a series of trapezoids with equal altitudes the area of which can be obtained by one computation. Although there are several approximate rules for this computation the two most common are what are known as the *Trapezoidal Rule* and *Simpson's One-Third Rule*.

363. Trapezoidal Rule. — If the figure is considered as made up of a series of trapezoids their area can be found by the following rule: —

$$\text{Area} = d \left(\frac{h_e}{2} + \Sigma h + \frac{h'_e}{2} \right)$$

where d = common distance between offsets,
 h_e and h'_e = end offsets of the series of trapezoids,
 and Σh = sum of the intermediate offsets.

364. Simpson's One-Third Rule. — In the development of this formula the curved line is assumed to be a parabolic curve. It is claimed by some that this affords results more nearly correct than the Trapezoidal Rule, although for most problems of this kind, where the offsets at best can give but an approximate location of the boundary, frequently a brook or crooked wall the center of which must be estimated, it is quite probable that the Trapezoidal Rule is sufficiently exact. Simpson's One-Third Rule is as follows: —

$$\text{Area} = \frac{d}{3} (h_e + 2\Sigma h_{\text{odd}} + 4\Sigma h_{\text{even}} + h'_e)$$

where d = common distance between offsets,
 h_e and h'_e = end offsets of the series,
 $2 \Sigma h_{\text{odd}}$ = twice the sum of all the odd offsets
 (the 3d, 5th, 7th, etc., from the end)
 $4 \Sigma h_{\text{even}}$ = four times the sum of all the even offsets (the 2d, 4th, 6th, etc., from the end).

For this rule to apply there must be an **even** number of trapezoids; if there is an odd number, an even number of them may be computed by this rule and the extra trapezoid must be computed separately. Or, if there is a triangle or trapezoid at the end of this series, which has a base greater or less than d , it must also be computed separately.

Fig. 148 shows the computation of a series by both methods and also the computation of several trapezoids and triangles at the ends of the series. The data are taken from the field notes in Fig. 53, p. 104.

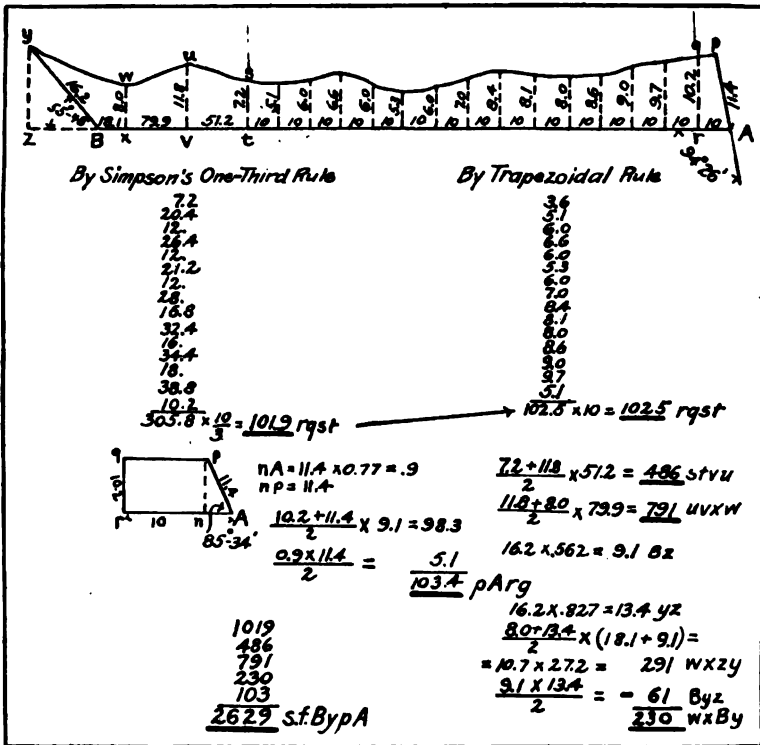

FIG. 148.

365. STRAIGHTENING CROOKED BOUNDARY LINES. — In Fig. 149, *AEFGH* represents a curved boundary between two

FIG. 149. STRAIGHTENING A CROOKED BOUNDARY.

tracts of land, and it is desired to run a line from *A* so as to make the boundary a straight line and to leave each tract of the same area as before.

The trial line *AB* is first run, and the distance *AB*, the angles at *A* and *B*, and the necessary offsets to the curved boundary are measured in the field. Then the areas of the property between this trial line and the curved line are computed as explained in the previous articles. The sum of the fractional areas on one side of the trial line and the sum of the areas on the other side of it should be equal. If not made so by the trial line, the difference between these sums is the area of a correction triangle *ABC* which must be taken from one tract and added to the other because the trial line has taken this difference from one of the tracts and it should therefore be restored. The area and the base *AB* being known the altitude *dC* can be computed. Then in the triangle *ABC*, the lines *BC* and *AC* and the angle at *A* are calculated; and the line *AC* is staked out, its calculated length being checked by measuring the line *AC* in the field and the angle at *A* being checked by the measured distance *BC*.

366. AREA BY TRIANGLES. — If the field has been surveyed by setting the transit in the middle of the field and taking angles between the corners (Art. 138, p. 105), the areas of the triangles may be found by the trigonometric formula:

$$\text{Area} = \frac{1}{2} a b \sin C,$$

where *C* is the angle included between the sides *a* and *b*.

If all three sides of any of the triangles have been measured

or if the field has been surveyed with the tape alone (Art. 139, p. 106), the area of the triangles can be found by the trigonometric formula:—

$$\text{Area} = \sqrt{s(s-a)(s-b)(s-c)}$$

where a , b , and c are the sides and $s = \frac{a+b+c}{2}$.

367. AREA OF A QUADRILATERAL BY TRIANGLES.—

Most city lots have four sides, and while the Double Meridian Distance Method (Art. 384, p. 352) is often employed in computing their areas, it is not at all uncommon in computing such quadrilateral lots to divide them into triangles, checking the fieldwork and computations, and computing the areas by triangles.

In Fig. 150, $ABCD$ represents an ordinary city lot in which all the sides and angles have been measured. It is evident that the diagonal BC can be computed either from BD , CD , and the angle D , or from AB , AC , and the angle A . These two determinations of BC should check each other. Similarly two independent determinations of AD can be found. These evidently check all the fieldwork and calculations as far as they have gone. In computing these triangles the best way is to resolve all the work into right triangle calculations, as suggested by the dotted lines on the figure.

FIG. 150.

Not only is this method more simple than to use the oblique triangle formulas, but it gives at the same time altitude distances which are useful in computing the area of the lot. The area can be obtained by calculating the area of one pair of triangles and readily checked by calculating the other pair.

These formulas are fairly accurate when M is very small as compared with C . They are most useful, however, as a check on computations made by the preceding method.

369. ROUGH CHECKS ON AREAS. — If the traverse has been plotted to scale, it can be easily divided into simple figures such as rectangles or triangles, their dimensions scaled from the plan, and their areas computed, thereby giving an independent rough check on the area.

A piece of tracing cloth divided into small squares can be placed over the plan of the traverse and the number of squares counted and the fractional parts estimated, generally to tenths of a square, by inspection. Then the area of one square being known an approximate area of the traverse may be obtained.

370. Planimeter. — One of the commonest ways of checking the area of a traverse is to obtain its area by means of an instru-

DB = Tangent Offset for chord CB .
 OE is drawn perpendicular to CB .
 In the two similar triangles OEB and CBD ,
 $DB : CB = BE : OB$
 $DB : CB = \frac{CB}{2} : OB$
 $DB = \frac{CB^2}{2 OB}$

FIG. 152.

Offset from Tangent = $\frac{(\text{Chord})^2}{2 \times \text{Radius}}$ (1)

But $DB = CH$, and $AB = 2 \times CB$ (approximately)

$$\therefore CH = \frac{\left(\frac{AB}{2}\right)^2}{2 OB} = \frac{AB^2}{8 OB} \quad (\text{approximately})$$

Middle Ordinate = $\frac{(\text{Chord})^2}{8 \times \text{Radius}}$ (approximately) (2)

The following will give some idea of the accuracy of this formula:

When radius = 20 ft. and chord = 10 ft., $M = 0.625$, (correct value is 0.635).

When radius = 100 ft. and chord = 25 ft., $M = 0.781$, (correct value is 0.784).

When radius = 100 ft. and chord = 100 ft., $M = 12.500$, (correct value is 13.397).

When radius = 1000 ft. and chord = 100 ft., $M = 1.250$, (correct value is 1.251).

It is evident from the above that this formula will not give accurate results when the chord is large in comparison with the radius.

ment called the *planimeter*. It is a small instrument consisting of an arm, carrying a tracing point, which is fastened to the frame of the instrument; the arm can be adjusted to any desired length. The frame touches the paper at only three points; the anchor point, the tracing point, and the circumference of a small wheel which is free to revolve. On the rim of this wheel is a scale and beside it is a vernier which is used in reading the scale. The length of the arm can be regulated by setting it at the proper reading on a scale which is marked on the arm, so that a unit on the wheel scale will represent any desired unit area such as a square inch or a square centimeter. (See Appendix B on the Planimeter.)

In using the instrument the anchor point is set at some convenient position on the drawing **outside** of the area to be measured and then the tracing point is run around the perimeter of the area to be determined. The reading on the wheel is recorded when the tracer is at the starting point. The tracer, in passing around the perimeter, should be kept as **closely as possible** on the boundary line and should return **exactly** to the starting point. Then the scale is again read, and the difference between the two readings is the area which has been traced out, expressed in some unit depending on the length of the arm. The result can be easily transposed into the unit of the scale of the map.

Usually the settings for the scale on the arm are furnished by the maker for various units of area. It is safer to test this setting by running the instrument around a known area, such as 4 square inches and determining the interval passed over by the wheel by making several tests and by setting the anchor point at different positions. This interval divided by 4 will be the value of one square inch of plan area and this is equivalent to a certain number of square feet of surface, depending upon the scale of the map. It is important that the sides of the trial square should be laid off so that they agree with the present scale of the map which, owing to swelling or shrinking of the paper, is frequently not quite the same as when it was first drawn (Art. 479, p. 428).*

* When areas are desired from U. S. Geological Survey maps on which are shown parallels of latitude and longitude it is best to refer all planimetered areas to the areas of a quadrilateral, say, 1° on a side. The area of such quadrilateral

371. DEFLECTION ANGLES AND CHORDS FOR A CIRCULAR CURVE. — The computations shown in Fig. 153 refer to the notes in Fig. 104, p. 237. In the discussion of the simple curve as

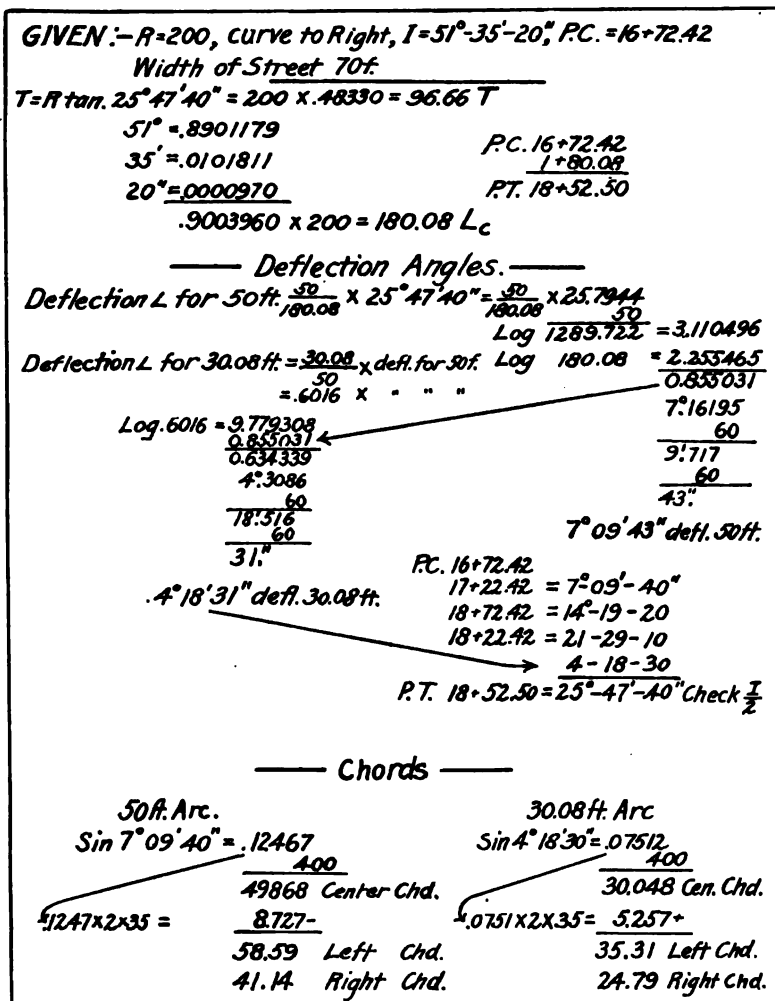

FIG. 153.

can be taken from a publication entitled Geological Tables and Formulas, by S. S. Gannett, Bulletin No. 232, U. S. Geological Survey, and by simple proportion the desired area found.

applied to city surveying (Art. 259, p. 234) will be found the formulas which have been used in the computations in Fig. 153. The length of the curve L_c is found by taking from Table VI, ("Lengths of Circular Arcs: Radius = 1"), the length of an arc for 51° , for $35'$, and for $20''$ successively and adding them, which gives the arc of a curve whose radius is 1 and whose central angle is $51^\circ 35' 20''$. This is then multiplied by the radius (200) which gives the value of L_c , which is added to the station of the P.C. to obtain the station of the P.T.

372. COMPUTATION OF OBSERVATIONS. — The computations relating to observations for meridian and latitude will be found in Chapter VII.

COMPUTATION OF VOLUME.

373. BORROW-PITS.* — Fig. 154 is a plan of a portion of a borrow-pit, at the corners of which the depth of excavation is marked in feet and tenths. Each of the regular sections of earthwork is a truncated rectangular prism whose volume is equal to the average of the four corner heights multiplied by the area of the cross-section, or expressed as a formula,

$$\text{Volume Truncated Rectangular Prism} = A \times \frac{h_1 + h_2 + h_3 + h_4}{4}$$

where A is the area of the cross-section and h_1 , h_2 , h_3 , and h_4 are the corner heights.

For a truncated triangular prism such as abc , using the same notation,

$$\text{Volume Truncated Triangular Prism} = A \times \frac{h_1 + h_2 + h_3}{3}$$

In computing a trapezoidal prism, such as $fdhg$, the trapezoid is subdivided into a rectangle feh and a triangle fde ; or for jhd s, into two triangles by diagonal lines, as jhs and hds and their volumes may be computed by the above formula.

When there are several prisms with the same cross-section, as shown in Fig. 154, these rectangular prisms can be computed as one solid by assembling them as follows: — multiply each corner

* For a complete discussion of the computation of Borrow-Pits see *Railroad Curves and Earthwork* by Professor C. F. Allen, published by Spon & Chamberlain, New York.

height by the number of rectangular prisms in which it occurs and then add these results and divide by 4. This is then multiplied by the area of the cross-section of one prism. For example, in Fig. 154, the quantity bounded by *amnrjsja* can be found by

FIG. 154. PLAN OF PORTION OF A BORROW-PIT.

one computation because it is composed of a series of prisms having the same cross-section. In the summation of the heights, those at *a*, *m*, *n*, *r*, and *s* are taken but once, those at such points as *c*, *g*, *h*, etc. are multiplied by 2, at *j* the height is multiplied by 3, and at such points as *k* it is multiplied by 4.

Where the excavation is completed to a certain level, as in a cellar, it is a special case of above. The area of the cellar can be

divided into rectangles, their corner heights taken, and from these the volume can be computed.

374. VOLUME OF PRISMOID. — The data obtained from field notes are usually in the form of cross-sections which are taken at right angles to some general line of the construction, thereby dividing the earthwork into prismoidal solids with their bases parallel and their sides either plane or warped surfaces. The bases of the solids are the cross-sections which are obtained by taking sections of trench excavation or of road construction (Figs. 91 and 92, p. 208).

375. End Area Formula. — The simplest method of computing the volume of a prismoidal solid is to average the areas of the two bases and multiply by the distance between them, which, expressed as a formula, is

$$V = \frac{A_1 + A_2}{2} \times l \quad (\text{End Area Formula})$$

in which A_1 and A_2 are the areas of the two end bases and l is the distance between them. This method is used to a very great extent throughout the country, although it does not give sufficiently accurate results for certain classes of work.

376. Prismoidal Formula. — The correct volume of a prismoid is expressed by the *Prismoidal Formula*:

$$\text{Volume of Prismoid} = \frac{l}{6} (A_1 + 4A_m + A_2)$$

in which l is the distance between the two bases, A_1 and A_2 ; and A_m is the "middle area," i.e., the area half-way between the two bases, which is obtained by averaging the corresponding dimensions of the two end areas, A_1 and A_2 ; it should not be taken as the mean of A_1 and A_2 .

377. The end areas can easily be computed by dividing them into triangles as shown in Fig. 155, the area of which can be found readily from the dimensions given in the field notes.

FIG. 155.

$$\text{Notes of section: } \frac{29.0}{+6.0} + 4.0 \frac{21.5}{+1.0}$$

$$\begin{aligned} \text{Area} &= \frac{4 \times (21.5 + 29)}{2} + \frac{20 \times (1 + 6)}{2} \\ &= 2 \times 50.5 + 10 \times 7 = 171. \end{aligned}$$

It is also the custom with some surveyors to plot each section carefully to scale and to obtain its area by use of the planimeter (Art. 370, p. 339). This is probably the most practical method when the sections are very irregular since the field work does not warrant the use of very accurate methods.

There are several other methods employed in computing earthwork but the above are by far the most common.

Several sets of **Earthwork Tables and Diagrams** have been published which reduce the work of computation very materially.

378. ESTIMATES FOR GRADING.—Estimates for grading may be conveniently made by means of a topographic map. On this map will appear the contours of the original surface. The contours representing the finished surface are also sketched upon the map, and the smaller the interval between the contours the more accurate will be the result. In Fig. 156 the full lines represent the contours of the original surface which is to be altered so that when the necessary cutting and filling has been done the new surface will have the appearance indicated by the dash contours. At contour 20 and at contour 25 no grading is to be done. On the plan, first sketch the lines *ABCDEF* and *AGHIJB* which are lines of "no cut" and "no fill," i.e., lines which enclose areas that are either to be excavated or filled. The amount of excavation and embankment must be computed separately. In sketching such lines the lines *AB*, *ED*, and *III*, as will be seen, follow the intersection of the original contours with the new ones, since at these points there is no cut or fill. There are no direct data on the plan which define where the earthwork ends at *C* but the assumption is here made that the fill will run out to meet the original surface at about the next contour at *C*. In this example the fill must run out somewhere between the 24-ft. contour and the 25-ft. contour, for if it ran beyond the 25-ft.

contour there would be another new 25-ft. contour shown on the plan. Therefore the line *BCD* has been sketched to represent the limits of the fill in that vicinity; similarly *EFA*, *AGH*, and *IJB* have been sketched.

There are three general methods of computing the earthwork from the data given on the plan; (1) by computing directly the amount of cut or fill between successive contours, (2) by

FIG. 156.

assuming a horizontal plane below the lowest part of the earthwork and computing the volume of the earth between this plane and the original surface, then computing the volume between the same plane and the finished surface; the difference between these two volumes will be the amount of earthwork, or (3) by drawing on the plan a line of no cut or fill, a line representing,

say, 5 ft. cut or fill, a line representing 10 ft. cut or fill and so on. Then compute the volume between these successive 5-ft. layers.

379. (1) Referring to Fig. 156 and applying the first method, the volume of the solid *AMPE* is that of a solid having two parallel end planes *AKEL* (a plane at elevation 21) being the lower, and *MNPO* (a plane at elevation 22) being the upper plane. The altitude between these two end planes will be the difference in elevation between 21 and 22, or will be 1 ft.

The areas of the horizontal planes *AKEL*, *MNPO*, *QRST*, and *BUDV* may be obtained by planimeter (Art. 370, p. 339) or otherwise, and the volume of the solid *AKEL-MNPO* may be obtained by the End Area Method (Art. 375, p. 344), its altitude being 1 ft. If it is desired to obtain the volume by the use of the Prismoidal Formula the volume of the solid *AKEL-QRST* may be found by using *AKEL* as one base, *QRST* as the other, and *MNOP* as the middle area, the altitude, or length, of the solid being the difference between 21 and 23, or 2 ft. The solid *AKEL-F* may be considered to be a pyramid with a base *AKEL* and an altitude equal to the vertical distance between the contour 21 and the point *F* which is in this case on contour 20, or a vertical distance here of 1 ft.

EXAMPLE.

In Fig. 156 the amount of fill on the area *ABCDEF* is computed below.

Area <i>AEK</i> = 900 sq. ft.	$900 \times \frac{1}{3} = 300$ cu. ft. (Pyramid)
" <i>MNPO</i> = 1000	$\frac{900 + 1000}{2} \times 1 = 950.$
" <i>QRST</i> = 1020	$\frac{1000 + 1020}{2} \times 1 = 1010.$
" <i>BUDV</i> = 680	$\frac{1020 + 680}{2} \times 1 = 850.$
	$680 \times \frac{1}{3} = 227$ (Pyramid)
	$\begin{array}{r} 3 \overline{) 3337} \text{ cu. ft.} \\ 9 \overline{) 1112} \end{array}$
	124. cu. yds. Total Fill.

380. (2) Referring again to Fig. 156 and applying the second method, the area of *ABCDEF* is found (by planimeter); this is the area of a plane at, say, elevation 20, since none of the fill

extends below contour 20. Then the area of $ABCDEL$ is found, which is the area of the plane cutting the original ground at elevation 21. Similarly the areas of $MBCDPO$, $QBCDST$, and $BCDV$ are found. The volume of the solids between these planes may be computed by the End Area Method or by use of the Prismoidal Formula, in which case every other contour plane is used as a middle area as explained in the preceding paragraph. The volume of solid whose base is $BCDV$ is a pyramid whose altitude is the vertical distance between the 24-ft. contour and point C , which in this case is 1 ft.

By the same general method the areas of $ABCDEK$, $MBCDPN$, etc., which refer to the new surface of the ground, may be obtained, and the volume of the solids between successive contour planes computed. The difference between this quantity and the quantity between a plane at elevation 20 and the original surface will give the amount of fill.

While in this particular problem the first method is the shorter, still there are cases where the second method will be somewhat simpler. It is particularly useful when the actual amount of cut or fill is not desired but when it is required to know if the proposed alterations will require more or less earth than can be easily obtained on the premises and, if so, about how much the excess will be. In this case the portions of cut and fill will not have to be computed separately. A line is drawn around the limits of the entire area where the grading is to be done, the volume between an assumed plane and the original surface is found, and then the volume between the same plane and the proposed surface. The difference between the two values will give the amount of excess of earthwork.

381. (3) Fig. 157 illustrates a third method of computing earthwork from the data given on a topographic map. The original contours are shown in full lines and the contours of the proposed surface in dash lines. Through the intersection of the new contours with the original ones is drawn the line of "no cut" (zero line), the line where the cut is just 5 ft. (marked 5), the line of 10 ft. cut (marked 10), etc. These dotted curves enclose areas which are the horizontal projections of irregular surfaces which are parallel to the final surface and at 5 ft., 10 ft.,

FIG. 157.

15 ft., etc., above the final surface. The solids included between these 5 ft. irregular surfaces are layers of earth each 5 ft. thick, and their volumes may be computed by either the End Area Method or by the Prismoidal Formula as explained in the preceding methods. The areas of these horizontal projections are obtained from the map and the vertical dimensions of the solids are the contour intervals.

382. ROUGH ESTIMATES. — Rough estimates of the quantity of earthwork are often required for preliminary estimates of the cost of construction or for monthly estimates of the amount of work done. For preliminary estimates of road construction, very

frequently the notes of alignment and the profile of the center line are the only information at hand. From this profile the center cuts or fills can be obtained, and the cross-sections can be assumed to be level sections (Art. 232, p. 209) and computed by the End Area Method. The slight errors resulting will be corrected in the final estimate.

In obtaining the required data from which to make an approximate estimate of the quantity of earthwork, the engineer has an opportunity to exercise his judgment to an unusual degree. Rough estimates do not, as a rule, call for a large amount of field-work. It is important that as few measurements as possible should be taken and that these should also be at the proper places to give complete data and to allow simple computations. Too often engineers, as soon as they arrive on the work and before making a study of their problems, begin to take measurements, consequently they return to the office after hours of hard work with a mass of figures from which it will take several more hours to compute the quantities. Whereas, a few moments' thought given to the choosing of the proper measurements to be taken in the field would give data which could be computed in a few moments by use of the slide rule, affording results sufficiently accurate for rough estimates.

PROBLEMS.

1. A series of perpendicular offsets are taken from a straight line to a curved boundary line. The offsets are 15 ft. apart and were taken in the following order: 6.8, 7.2, 4.6, 5.7, 7.1, 6.3, and 6.8.

(a) Find the area between the straight and curved lines by the Trapezoidal Rule.

(b) Find the same area by Simpson's One-Third Rule.

2. It is desired to substitute for a curved boundary line a straight line which shall part off the same areas as the curved line. A trial straight line AB has been run; its bearing is $S 10^{\circ} 15' W$, its length is 418.5 ft., and point B is on a boundary line CD which has a bearing $S 80^{\circ} W$. The sum of the areas between the trial line and the crooked boundary on the easterly side is 2657. ft.; on the westerly side it is 7891. ft. It is required to determine the distance BX along CD such that AX shall be the straight boundary line desired. Also find the length of the line AX .

3. In the quadrilateral $ACBD$ the distances and angles which were taken in the field are as follows:

$$\begin{array}{ll} AB = 50.63 & \angle B = 105^{\circ} 39' 00'' \\ BC = 163.78 & \angle A = 89^{\circ} 37' 30'' \\ CD = 93.80 & \\ DA = 160.24 & \\ DB = 167.73 & \end{array}$$

Check the fieldwork by computations, and figure the area of the quadrilateral by using right triangles entirely.

4. Two street lines intersect at an angle (deflection angle) of $48^{\circ} 17' 30''$. The corner lot is rounded off by a circular curve of 40-ft. radius.

(a) Find the length of this curve to the nearest $\frac{1}{16}$ ft.

(b) Find the area of the land included between the curve and the two tangents to the curve (the two street lines produced).

5. Find the quantity in cubic yards, in the borrow-pit shown in Fig. 154; the squares are 25 ft. on a side, and the line ast is straight.

6. At station 6 a rectangular trench was measured and found to be 3 ft. wide and 4 ft. deep. At station 6+70 it was found to be 3.2 ft. wide and 8.6 ft. deep.

(a) Find by use of the Prismoidal Formula the quantity of earthwork between stations 6 and 6+70. Result in cubic yards.

(b) Find the volume of the same by End Area Method.

7. The following is a set of notes of the earthwork of a road embankment.

$$\begin{array}{rclcl} 12 & \frac{27.0}{+ 8.0} & + 4.2 & \frac{23.4}{+ 5.6} \\ 11 + 60 & \frac{30.0}{+ 10.0} & \frac{15.0}{+ 4.5} & + 4.0 & \frac{15.0}{+ 7.5} & \frac{24.0}{+ 6.0} \\ \text{Sta. 11} & \frac{21.0}{+ 4.0} & + 6.0 & & \frac{25.8}{+ 7.2} \end{array}$$

The base of the road is 30 ft. and the slopes are $1\frac{1}{2}$ to 1.

Find by the End Area Method the quantity of earthwork from Sta. 11 to 12. Result in cubic yards.

CHAPTER XIII.

AREA BY DOUBLE MERIDIAN DISTANCES.—COÖRDINATES.

383. COMPUTATION OF AREA. — The computation of the area of any piece of property which has been surveyed as a traverse will in general consist of (1) the computation of the area enclosed by the traverse and (2), where the traverse does not follow the property line, the computation of fractional areas to be added to or subtracted from the area of the traverse as the case may be.

384. COMPUTATION OF AREA BY DOUBLE MERIDIAN DISTANCE METHOD. — In the field notes the length and the bearing of each line of the traverse are recorded. To obtain the area enclosed the points of the survey are referred to a system of rectangular coördinates. In Fig. 158 the coördinate axes chosen are the magnetic meridian through the most westerly point *F*, and a line through *F* at right angles to the meridian. In compass surveys it is convenient to use the magnetic meridian for one of the axes; in transit surveys the true meridian is often used when its direction is known, but any arbitrary line may be used as an axis and some convenience results from choosing one of the lines of the survey as one of the axes.

In computing the area, first find the length of the projection of each line on each of the coördinate axes, or in other words, find the *northing* or *southing* and the *easting* or *westing* of each line, or *course*, of the traverse. The projection of any line on the meridian is called its *difference of latitude* or simply its *latitude*. The projection of a line on the other axis is called its *difference of departure*, or simply its *departure*.* In Fig. 158 the latitude of *FA* is *Fq*; the departure of *FA* is *qA*. The latitude and departure of each course are computed by solving the right triangle formed by drawing lines through the extremities of this course

* Some authors use the terms *latitude difference* and *longitude difference*.

FIG. 158.

and parallel to the coördinate axes. It is evident from the figure that

$$\begin{aligned} \text{Latitude} &= \text{Distance} \times \cos \text{Bearing.} \\ \text{and} \quad \text{Departure} &= \text{Distance} \times \sin \text{Bearing.} \end{aligned}$$

Latitudes are called *North* or *South* and departures *East* or *West*, depending upon the direction of the course as shown by its letters, e.g., if the bearing is N 30° E this course has a North latitude and an East departure. North latitudes and East departures are considered as *positive* (+); South latitudes and West departures

as *negative* (—). In the figure the courses are assumed to run from *F* to *A*, from *A* to *B*, etc.

385. After all of the latitudes and departures have been computed (supposing for the present that the traverse is a closed

FIG. 158

figure) proceed to find the areas of all the trapezoids or triangles, such as *DErs*, *EFr*, etc., formed by (1) the courses, (2) their projections on the meridian, and (3) the perpendiculars

from the extremities of the courses to the meridian. It is evident in the figure shown that the area of the field is equal to

$$(AB\ wq + BC\ tw + CD\ st) - (DE\ rs + EF\ r + FA\ q),$$

that is, in this figure the sum of all the areas determined by lines running northward minus the sum of all the areas determined by lines running southward. These are known as *north areas* and *south areas*.* In computing the areas of these trapezoids it is convenient as well as customary to find the *double areas* and divide the final result by 2 instead of dividing by 2 in figuring each trapezoid. The area of any trapezoid equals the average distance of the extremities of the course from the meridian, multiplied by the length of the projection of the course on the meridian. This average distance of the ends of the line from the meridian is known as the *meridian distance* of the course, i.e., the meridian distance of the middle point of the course. In computing the double areas, twice this distance, or the *double meridian distance* (D.M.D.), is used, which is equal to the sum of the distances of the ends of the course from the meridian. In arranging the data for computing the double meridian distances, the courses must be tabulated in consecutive order around the traverse, whether they were so taken in the field or not. The D.M.D. of the course *FA* is *qA* which is the departure of the course *FA*. The D.M.D. of *AB* is *qA + wB = qA + qA + zB*, i.e., the D.M.D. of course *FA* + the dep. of *FA* + the dep. of *AB*. The D.M.D. of *BC* = *tC + wB = tC + vC + qA + zB = qA + wB + zB + vC = D.M.D. of AB + dep. of AB + dep. of BC*.

Hence the D.M.D. of all of the courses may be computed by the following rules:—

(1) The D.M.D. of the first course (starting from the primary meridian†) equals the departure of the course itself.

* If the traverse had been run around the field in the opposite direction these north areas would become south areas. The result would be the same, however, in either case since it is the algebraic sum of the areas which is obtained.

† Any meridian could have been chosen as the primary meridian, but negative signs are avoided if the most westerly point is chosen as the starting point.

(2) The D.M.D. of any other course equals the D.M.D. of the preceding course plus the departure of the preceding course plus the departure of the course itself.

(3) The D.M.D. of the last course should be numerically equal to its departure, but with opposite sign.

The double areas of all the trapezoids may now be found by simply multiplying the D.M.D. of each course by the latitude of the same course, North latitudes being regarded as *plus* and South latitudes as *minus*. The sum of all the north double areas minus the sum of all the south double areas equals twice the area of the field. Be careful to **divide by 2** after completing the other details of the computation.

386. COMPUTATION FOR AREA OF COMPASS SURVEY BY D.M.D. METHOD. — The details of the above are illustrated in Fig. 159, which is the computation of the area of the traverse given in the compass notes in Fig. 50, p. 100. It will be seen from a study of the notes that there was local attraction of $\frac{1}{2}^\circ$ at station *B*, and that in the following computations the corrected bearings are used (Art. 41, p. 30).

In Fig. 159 the bearings, distances, latitudes, departures, and D.M.D.'s, which are recorded on a line with station *F* are those corresponding to the course *FA*; those recorded on a line with station *A* refer to the course *AB*; etc. After the bearings and distances are entered in the table the places which are to be blank in the remaining columns are cancelled as shown; this is a check against putting the results of the computations in the wrong spaces. In computing the latitudes and departures the *log distance* is first entered; the *log sin bearing* is written below this and the *log cos bearing* is recorded above. To obtain the *log latitude* add the upper two logarithms; to obtain the *log departure* add the lower two logarithms. When the latitude and departure of a course have been obtained see if the results appear to be consistent with the given bearing and distance; when the bearing of a course, for example, is less than 45° its latitude is greater than its departure and *vice versa*.

FIG. 160. AREA OF COMPASS AND CHAIN SURVEY BY DOUBLE MERIDIAN DISTANCE METHOD.

387. Balancing a Chain and Compass Traverse. — Before the D.M.D. method can be properly applied the errors of measurement of the traverse should be so distributed that the figure becomes a closed polygon. If the field is a closed polygon the sum of the north latitudes will equal the sum of the south latitudes, and the sum of the east departures will equal the sum of the west departures. As soon as the latitudes and departures are computed this test is applied. If the sums differ, the error is distributed in such a way as to make the sums exactly equal, and at the same time to give to each latitude and departure its most probable value. In the case of a compass survey the errors are fully as likely to be in the bearings, which have been read to the nearest quarter of a degree, as in the distances; hence if nothing definite is known in regard to the errors they are assumed to be proportional to the lengths of the lines and the survey is balanced by the following rule which alters not only the lengths of the lines but also their directions.

388. *The correction to be applied to the $\left\{ \begin{array}{c} \text{latitude} \\ \text{departure} \end{array} \right\}$ of any course is to the total error in $\left\{ \begin{array}{c} \text{latitude} \\ \text{departure} \end{array} \right\}$ as the length of the course is to the perimeter of the field.*

This rule is based upon purely mathematical considerations and should be applied **only** when nothing is known as to where the errors probably occurred. Usually the surveyor knows where the error is probably greatest and consequently in balancing the survey he will place the largest corrections where, in his judgment, they belong. In measuring with the chain, the recorded distances tend always to be too long, because the sag, poor alignment, and poor plumbing, all serve to shorten the chain; consequently the probability is that the recorded measurements are too long, therefore in balancing it is more logical to subtract from the latitudes and departures in the columns whose sums are greater rather than to add anything to the latitudes and departures in the smaller columns. The corrections should of course be applied in such a way as to decrease the difference

between the two columns. In the example (Fig. 159) the total error in latitude is 0.08 and the total error in departure is 0.07. The perimeter of the traverse is 129.77. Hence the correction per chain-length is 0.062 links for latitudes, and 0.054 for departures. The corrected values of the latitudes and departures are given in the columns headed *balanced latitudes* and *balanced departures*.

389. From the balanced departures we then compute the D.M.D. of each course as shown in the next column. Observe that the last D.M.D. (point *F*), as computed from the preceding one, is exactly equal to the departure of the last course. This checks the computation of the D.M.D.'s. The D.M.D.'s are now multiplied by their corresponding latitudes and the products placed in the *double area* columns, those having N latitudes being placed in the column of north (+) double areas and those having S latitudes in the column of south (−) double areas. The sums of these columns differ by 2245.8. One-half of this, or, 1123. is the area of the field in square chains, which equals 112.3 acres.

By proceeding around the field in the reverse direction the letters of all of the bearings would be changed, in which case the column of south double areas would be the larger.

390. **Double Parallel Distance.** — There is no particular reason for using the trapezoids formed by projecting the courses on to the meridian rather than those formed by projecting them on to the other axis. In the latter case the *Double Parallel Distance* (D.P.D.) should be computed, and the result multiplied by the departure for each course.

In the D.M.D. method the computations have been checked at every step with the exception of the multiplication of the D.M.D.'s by the latitudes. A check on this part of the work can be obtained by figuring the area by use of the D.P.D.'s. This furnishes an example of a very desirable method of checking, as a different set of figures is used in computing the double areas, and the opportunity for repeating the same error is thus avoided. Fig. 160 shows the computation by the D.P.D. method of the area of the same survey as is calculated by the D.M.D. method in Fig. 159.

FIG. 160. AREA OF COMPASS SURVEY BY DOUBLE PARALLEL DISTANCES.

391. Error of Closure. — An indication of the accuracy of the survey is found in the *error of closure*. If a complete traverse of the field has been made the final point, as computed, should coincide with the first. The amount by which they fail to coincide is the total error of the survey and may be found by the formula

$$E = \sqrt{l^2 + d^2}$$

where l is the error in latitude and d is the error in departure. If this distance E is divided by the perimeter of the field the resulting fraction is called the *error of closure*, which in this survey is approximately $\frac{1}{1300}$ (see Art. 132, p. 99).

392. COMPUTATION OF AREA OF A TRANSIT AND TAPE SURVEY. — The field notes show the lengths of the sides of the traverse, all of the angles and perhaps the magnetic bear-

ings of some or all of the courses. If an observation has been made for determining the direction of the meridian, this affords the means of computing the true bearings of all of the traverse lines.

393. The first step in reducing the notes (provided it has not already been done in the field) is to see if the difference between the sum of the right and left deflection angles equals 360° . If interior angles have been measured, their sum should equal the number of sides of the field times two right angles, minus four right angles. If there is a small error in the sum of the angles this is usually adjusted by placing the error in the angles where it probably occurred. If nothing is known as to where it probably occurred the corrections should be made in the angles adjacent to the **short** lines, as any error in sighting or setting up the transit causes a greater angular error in a short line than in a long one.

The transit survey is referred to a system of rectangular coördinates, as in case of the compass survey. If the direction of the true meridian is known (either from a special observation or by connection with some other survey referred to the meridian), it is advisable to use this meridian as one of the coördinate axes. If the direction of the true meridian is not known the magnetic meridian may be used. This of course is convenient in some respects because the bearings taken in the field already refer to this meridian. If not even the magnetic meridian is known it will then be advisable to choose some line of the survey (preferably a long one) as the axis, for using one of the traverse lines as an axis saves computing the latitude and departure of one course.

Whatever line is chosen as an axis, the bearings used for computing the latitudes and departures are to be obtained from the **measured angles** (after correction), and **not** from the observed bearings. For instance, if some line is selected and its magnetic bearing used, then the bearings of all of the other lines should be computed from this one by means of the (corrected) transit angles. In this way the bearings are relatively as accurate as the transit angles, even though the whole survey may be referred to an erroneous meridian due to the error of the magnetic

161 A.

(These computations go with Fig. 161.)

bearing of the first line. In calculating these bearings the work should be checked by computing the bearing of each line from that preceding, the bearing of the last line being followed by the calculation of a new bearing of the first line of the traverse which must agree with the magnetic bearing assumed for it, provided the deflection angles have been adjusted so that their algebraic sum is 360° . The observed magnetic bearings of the different courses will serve as a check against large mistakes in this calculation.

394. When all of the bearings have been figured the latitudes and departures are to be computed. In good transit surveys five places in the trigonometric functions will usually be necessary. If the angles are measured, by repetition, to a small fraction of a minute, seven-place logarithmic tables may profitably be em-

ployed, as much interpolation is avoided by their use, but the logarithms need not be taken out to more than five or six places. Seven places, of course, are more than are necessary so far as precision is concerned (Art. 351, p. 324).

The computation of the latitudes and departures may be conveniently arranged as shown in Fig. 161 which is the computation of the survey in Fig. 52, p. 103. After the latitudes and departures have been calculated they are arranged in tabular form. The columns of latitudes and the columns of departures are added and compared just as in a compass survey.

395. Balancing a Transit and Tape Traverse. — In adjusting (balancing) a transit traverse a different rule is used from the one given in Art. 388. In the case of a transit survey the error is chiefly in the measurement of distances, as it is much easier to secure accurate results in the angular work than in the tape measurements. Hence the following rule for balancing the survey is applicable: —

The correction to be applied to the $\left\{ \begin{array}{l} \text{latitude} \\ \text{departure} \end{array} \right\}$ of any course is to the total error in $\left\{ \begin{array}{l} \text{latitude} \\ \text{departure} \end{array} \right\}$ as the $\left\{ \begin{array}{l} \text{latitude} \\ \text{departure} \end{array} \right\}$ of that course is to the sum of all of the $\left\{ \begin{array}{l} \text{latitudes} \\ \text{departures} \end{array} \right\}$ (without regard to algebraic sign).

As in the case of a compass survey, the surveyor's knowledge of the circumstances should always take precedence over the rule, and it is probably more nearly correct to **shorten** the latitudes or departures in the larger columns than to **lengthen** them in the smaller columns. This is because distances are usually recorded longer than they actually are; the only cases where the distance is probably too short is when an excessive pull has been given to the tape or a mistake made in measurement. It will be observed in the original notes (Fig. 52, p. 103) that the distances *BC*, *GH*, and *KA* were all questioned, i.e., they were measured under such conditions that it is probable that there may be one or two hundredths error in them. In balancing the latitudes and departures then, this information is used. In Fig. 161 it will be seen that in balancing the survey the latitudes and departures

In balancing the angles, in which there was an error of 15 seconds, it will be noticed that the correction for this error, being small, was put into one angle, that at *C*, one of whose sides is the shortest line in the traverse. The area is computed as explained in Art. 385, p. 354.

396. **Fractional Areas.** — Fig. 162 is the computation of the

survey shown in Fig. 53, p. 104. The traverse was run with a transit and tape, the angles being measured to the nearest minute

and the sides to tenths of a foot. Nothing appears in the field notes to indicate that any of the lines were difficult to measure, so it is assumed that any errors in measurement are as likely to occur in one line as another. Therefore, in balancing the latitudes and departures of this survey, the rule given in Art. 395 is applied. In balancing the angles, in which there was an error of 1 minute, the entire error was placed in the angle at *D* where the side *DE* is short in comparison with the other sides.

It will be noticed that the distances which appear on the sketches in the computation are slightly different from those which appear in the field notes (Fig. 53); this is due to the fact that the distances have been corrected for erroneous length of tape before undertaking to calculate the area. The intermediate steps in the computation of this traverse do not appear in Fig. 162, but they are the same as in the last traverse. The D.M.D.'s were computed from *F*, the most westerly point. The computation of the fractional areas is also given.

397. SUPPLYING MISSING DATA. — If any two of the bearings or distances are omitted in the traverse of a field the missing data can be supplied and the area obtained by computations based on the measurements taken. As has been shown in Art. 387, p. 358, the algebraic sum of all the latitudes in a closed survey must equal zero, and the algebraic sum of all the departures must equal zero; or, to put it in the form of an equation,

$$\begin{aligned} Z_1 \cos A + Z_2 \cos B + Z_3 \cos C + \text{etc.} &= 0 \\ Z_1 \sin A + Z_2 \sin B + Z_3 \sin C + \text{etc.} &= 0 \end{aligned}$$

where Z_1, Z_2, Z_3 , etc., are the lengths of the corresponding courses. Therefore from these two equations any two unknown values in them can be computed.

The missing data could be any of the following combinations: —

- (1) The bearing and length of a line.
- (2) The length of a line and the bearing of another line.
- (3) The length of two lines.
- (4) The bearings of two lines.

398. Case (1) where the bearing and length of a line are missing is by far the most common. Its solution is also more direct than that of the other cases.

If the latitudes and departures of all of the measured sides are calculated, the sum of N and S latitudes will be found to differ, and the amount by which they differ is the latitude of the omitted side **plus** or **minus** the errors of latitudes. Similarly the amount by which the E and W departures differ is the departure of the course omitted **plus** or **minus** the errors of departures. From the latitude and departure of a course its length and bearing may be readily found.

A practical application of this case is found in the problems of subdividing a field by a line running from one known point to another, the direction and length of the dividing line not having been measured. The area of the portion cut off by this line can readily be computed by the above method. In case the angles were taken with the transit, the bearing of one line would be assumed to be correct and all other bearings computed to correspond.

It is evident from the above that in supplying missing data the observed measurements must be assumed to be correct, as there is no way of proving this from the computations. For this reason it is never advisable, when it can possibly be avoided, to supply missing data derived from computations on which a field check has not been obtained.

399. The solutions of the other three cases of missing data are not so simple, as they involve the use of simultaneous equations; they will not be discussed here.

400. Besides the four cases mentioned above there are some special cases which are capable of solution. In Fig. 163 the lines and angles measured are shown by full lines. The bearing of AB is given. Here one side and two angles are missing. The solution is as follows. In the triangle EAB find EB , EBA , and AEB . In the triangle EDC find EC , DCE , and DEC . Then in the triangle EBC , in which EC ,

FIG. 163.

EB , and EBC are known, find ECB , CEB , and BC . All the angles and sides are then known. Other special cases may be solved in a similar manner.

401. DETECTING MISTAKES. — Mistakes in fieldwork may often be detected by means of the calculations. One of the easiest mistakes to make in surveying is to omit a whole tape-length in counting. If such a mistake were made and the latitudes and departures were computed, the linear error of closure of the survey would prove to be about a tape-length. In order to find in which line this mistake probably occurred compute the bearing of this linear error of closure and examine the traverse to find a line having a bearing the same or nearly the same. The error in departure divided by the error in latitude equals the **tangent of the bearing of the line** which represents the error of closure of the traverse. The errors of the survey, of course, will prevent these bearings from agreeing exactly. If two mistakes have been made it may be difficult and sometimes impossible to determine where they occurred. When an error of this sort is indicated by the computation the line should be re-measured. It is bad practice to change an observed measurement because it is found by calculation to disagree with other measured distances.

It may, and frequently does, happen that there is more than one line in the traverse which has about the same bearing. In such a case it is impossible to tell in which of these lines the mistake occurred. But if a cut-off line is measured as was suggested in Art. 145, p. 109, and one portion of the survey balances, the other part will contain the mistake. By proceeding in this way the number of lines in which the mistake could occur is reduced so that its location can be determined and checked by field measurement.

402. THE SUBDIVISION OF LAND. — There are a great many different problems which may arise in the subdivision of land and which may be solved simply by the application of the principles of trigonometry. A few of these problems are so common and so frequently involved in the working out of more complicated cases that their solution will be given.

403. To Cut Off from a Traverse a Given Area by a Straight Line starting from a Known Point on the Traverse. — In Fig. 164, $ABCDE$ represents the traverse which has been plotted and whose area has been computed.

It is desired to cut off a certain area by a line running from F which is at a known distance from A or E . The line FG' is drawn on the plan so as to make the area $FG'DE$ approximately equal to the desired area. The line DG' is scaled off and the scaled distance used as a trial length. Then the side FG' and its bearing can be found by the method explained in Art. 398, p. 367, and the area $FEDG'$ computed in the usual manner. The difference between the required area and the area of $FEDG'$ is the amount to be added to or subtracted from $FEDG'$. If this correction area is a minus area then the triangle $FG'G$ will represent it. In this triangle the base FG' and its area being known the altitude hG and the distances GG' and FG can be readily computed. In the traverse $FGDE$, which is the required area, the length of the missing side FG and its bearing can be supplied.

FIG. 164.

Instead of using the trial line FG' the line FD might have been first assumed and the correction triangle would then be FDG . This method has the advantage of containing one less side in the first trial area, but the correction triangle is large, whereas in the method explained above the correction triangle is small which may be of advantage in that part of the computation.

404. To Cut Off from a Traverse a Given Area by a Line running in a Given Direction. — In Fig. 164, $ABCDE$ represents a closed traverse from which is to be cut off a given area by a line running at a given angle (BJK) with AB . On the plot of the

traverse draw the line $J'K'$ in the given direction cutting off $J'BCK'$ which is, as nearly as can be judged, the required area. Scale the distance BJ' and use this trial distance in the computations. Then compute the distance $J'K'$ and the area of $J'BCK'$ by the method suggested in Art. 400, i.e., by dividing $J'BCK'$ into two oblique triangles. The difference between

this area and the required area is then found, which is a correction trapezoid to be added to or subtracted from $J'BCK'$. In this case it will be assumed that it is to be added to $J'BCK'$.

In this correction trapezoid the area and one base $J'K'$ are known; also the base angles, J' and K' . From these data an approximate value for the altitude of the trapezoid can be obtained and the length of the other base $K''J''$ of the trapezoid computed from this altitude and the length of $J'K'$. Then the area of this trapezoid $J'K'K''J''$ can be accurately determined;

FIG. 164.

the difference between this and the required correction will be small and the dimensions of the second correction trapezoid $J''K''K'J'$ can probably be readily computed from its area and the length of $J''K''$ which are known. By successive trials, probably not more than two, the correct line JK can be found. If lines AB and CD are approximately parallel the trapezoid is nearly a parallelogram and its correct altitude can then be quickly determined.

405. To Find the Area Cut Off from a Traverse by a Line running in a Given Direction from a Given Point in the Traverse.—This problem may be readily solved by drawing a line from the given point in the traverse to the corner which lies nearest the other extremity of the cut-off line. The area of the traverse thus formed is then computed, and this area corrected by means of a correction triangle.

In Fig. 165, $ABCDEFG$ represents a plot of a field. It is desired to run the line from E in a given direction EH and to compute the area $HEFGAB$ cut off by this line. The latitude and departure of points B and E being known the bearing and length of BE and the area of $ABEFG$ can be computed. Then the area and the remaining sides of the triangle BEH can be obtained from BE and the angles at B and E .

FIG. 165.

It is obvious that the solution of such problems as these is greatly facilitated by plotting the traverse before attempting the computations.

CALCULATIONS RELATING TO TRAVERSES WHICH DO NOT CLOSE.

FIG. 166.

406. TO CALCULATE THE TOTAL DISTANCE BETWEEN END POINTS. — Fig. 166 represents the traverse $ABCDEF$ in which the distance AF and the angle BAF are desired. AB can be assumed as one of a pair of rectangular coördinate axes and the coördinates of point F (AH and HF) computed by the method explained in Art. 410, p. 373. AF and the angle BAF can then be easily found. This method is of service in checking traverse plots of this type.

407. CUT-OFF LINES. — The calculation of cut-off lines, like the line CF in Fig. 166, is the same problem as was explained in Art. 398, p. 367. The angles DCF and EFC have been measured in the field and the traverse $CDEF$ is thus complete except that the length of the line CF is unknown. The length of CF and the angle it makes with AB can be readily computed since the coordinates of C and F can be found.

408. COMPUTATION OF AZIMUTHS WHEN CHECKING ANGLES TO A DISTANT OBJECT. — In this kind of problem the coördinates of all the points along the traverse can be computed with reference to some coördinate axes. At *A* and *B* (Fig. 167) angles have been taken to *S*, and from these angles the coördinates of point *S*, referred to *AB* and a line perpendicular to *AB* as axes, can be computed (Art. 410, p. 373). Co-

FIG. 167.

ordinates of *S* referred to the same axes should have the same value when figured from *BC* as a base as when calculated from the base *CD* and so on. If, however, when computed by means of angles at *D* and *E*, the point falls at *S'*, and angles *E* and *F* give its location also at *S'* there is evidence of a mistake in the traverse at *D*. If the two locations of *S* and *S'* are such that a line between them is parallel to either *CD* or *DE*, the mistake was probably made in the measurement of the line parallel to *SS'* and the distance *SS'* should be approximately equal to the amount of the mistake in measurement. If, however, *SS'* is not parallel to either

CD or *DE* the mistake probably lies in the angle at *D*.

409. CALCULATION OF TRIANGULATION. — In a triangulation system the base-line is the only line whose length is known at the start. The sides of any triangle are found from the law of sines, i.e.,

$$\frac{\sin A}{\sin B} = \frac{a}{b}$$

$$\frac{\sin A}{\sin C} = \frac{a}{c}$$

$$\frac{a \sin B}{\sin A} = b$$

$$\frac{a \sin C}{\sin A} = c$$

Assuming a to be the base and the angles A , B , and C to have been measured the calculations are arranged as follows:

$$\begin{array}{rcl}
 (1) \log a \ (1400.74) & = & 3.1463575 \\
 (2) \text{Colog Sin } A \ (57^{\circ} 42' 16'') & = & 0.0729874 \\
 (3) \log \text{Sin } B \ (61^{\circ} 17' 53'') & = & 9.9430639 \\
 (4) \log \text{Sin } C \ (60^{\circ} 59' 51'') & = & 9.9418088 \\
 \hline
 \text{Sum of (1) (2) (3) } \log b & = & 3.1624088 \\
 \text{Sum of (1) (2) (4) } \log c & = & 3.1611537
 \end{array}$$

410. COÖRDINATES. — In many cities the coördinate system of surveying is used (see Chapter IX). In this system the position of each corner of the different lots is fixed by rectangular coördinates measured from two lines at right angles to each other.

Often the origin of coördinates O (Fig. 168) is so chosen that the whole city is in the first quadrant YOX . Distances measured parallel to XX' are usually called abscissas and those parallel to YY' ordinates.

The advantage of this system of surveying lies in the fact that since all surveys refer to the same reference lines, they are therefore tied to each other; and also in the fact that a lot can be relocated from the coördinates of

FIG. 168.

its corners even if all of the corner bounds have been destroyed.

Generally the coördinate lines run N and S, and E and W, but when city streets have been laid out at right angles to each other and not on N and S, and E and W lines, it may be more convenient to have the system of coördinates parallel to the street lines.

The coördinates of any unknown point are usually computed from the coördinates of some other point to which the unknown

point is tied by an angle and distance. The difference in coördinates between the known and unknown points will be obtained as follows:—

Difference in X = distance \times sin azimuth angle.

Difference in Y = distance \times cos azimuth angle.

Sometimes the unknown point is located by angles from two other known points, in which case the distance between the two points whose coördinates are known can be computed and then the distance from one of the known points to the unknown point. The problem is then in the form described in the previous paragraph.

FIG. 169.

411. TO DETERMINE THE AREA OF A FIELD BY RECTANGULAR COÖRDINATES.—The area of the field 1, 2, 3, 4 (Fig. 169) is equal to the trapezoids

$$(a, 1, 2, b) + (b, 2, 3, c) - (a, 1, 4, d) - (d, 4, 3, c).$$

Expressed as an equation in terms of the coördinates the area is

$$1, 2, 3, 4 = (y_1 - y_2) \frac{x_1 + x_2}{2} + (y_2 - y_3) \frac{x_2 + x_3}{2} - (y_4 - y_1) \frac{x_4 + x_1}{2} - (y_1 - y_2) \frac{x_1 + x_2}{2} \quad (1)$$

$$= \frac{1}{2} \{ y_1 (x_2 - x_4) + y_2 (x_3 - x_1) + y_3 (x_4 - x_2) + y_4 (x_1 - x_3) \} \quad (2)$$

From this equation is derived the following rule for obtaining the area of a closed field from the coördinates of its corners: —

(1) Number the corners consecutively around the field.

(2) Multiply each $\left\{ \begin{array}{l} \text{abscissa} \\ \text{ordinate} \end{array} \right\}$ by the difference between the

following and the preceding $\left\{ \begin{array}{l} \text{ordinates} \\ \text{abscissas} \end{array} \right\}$, always subtracting the

following from the preceding (or always subtracting the preceding from the following), and take half the sum of the products.

412. Fig. 170 is the computation, by coördinates, of an area

Sta.	Bearing	Dist. (Chains)	Latitude		Departure		Balanced		X	Y	Diff bet Adjacent Y's	Double Area	
			N+	S-	E+	W-	Lat.	Dep.				+	-
0	N 57° W	160	0.87	—	—	1.34	+0.87	-1.34	20.56	21.36	-5.36	—	110.2
1	S 37° W	153.2	—	12.24	—	9.23	-12.23	-9.22	19.22	22.23	+11.36	218.3	—
2	S 46½° E	4.53	—	3.11	3.28	—	-3.11	+3.28	10.00	10.00	+15.34	153.4	—
3	N 43½° E	13.75	9.97	—	9.46	—	+9.98	+9.47	13.28	6.89	-6.87	—	91.2
4	N 26° W	5.00	4.49	—	—	2.19	+4.49	-2.19	22.75	16.87	-14.47	—	329.2
												371.7	530.6
												371.7	371.7
												2158.9	2158.9
												79.5	Sq. Ch.
												7.95	Acres.

FIG. 170. COMPUTATION OF COMPASS SURVEY BY COÖRDINATES.

from the field notes. The origin of coördinates is 10 chains W and 10 chains S of station 2.

413. Equation (1) may be developed into the following form:

$$1, 2, 3, 4 = \frac{1}{2} (x_2 y_1 - x_1 y_2 + x_3 y_2 - x_2 y_3 + x_4 y_3 - x_3 y_4 + x_1 y_4 - x_4 y_1) \quad (3)$$

When this formula is to be used the coördinates may be arranged in the following simple manner:

$$1, 2, 3, 4 = \frac{1}{2} \left(\frac{x_1}{y_1} \times \frac{x_2}{y_2} \times \frac{x_3}{y_3} \times \frac{x_4}{y_4} \dots \times \frac{x_1}{y_1} \right) \quad (4)$$

From equation (3) it will be seen that the area is equal to the sum of the products of the ordinates joined by **full** lines in (4) **minus** the sum of the products of the ordinates joined by **broken** lines. This formula involves the multiplications of larger numbers than in (2), but does not require any intermediate subtractions.

PROBLEMS.

1. The latitude of a line of a traverse is $+106.42$ ft.; its departure is -273.62 . What is its bearing?
2. From the following notes of a compass survey, compute by the double meridian distance method the area in acres.

Station.	Bearing.	Distance (Chains).
A	N $46^{\circ}\frac{1}{2}$ W	20.76
B	N $51^{\circ}\frac{1}{4}$ E	13.80
C	East	21.35
D	S 56° E	27.60
E	S $33^{\circ}\frac{1}{4}$ W	18.80
F	N $74^{\circ}\frac{1}{2}$ W	30.98

3. In the following notes of a compass survey the length and bearing of one of the courses were omitted. Substitute the correct values and compute the area (in acres) by the double meridian distance method.

Station.	Bearing.	Distance (Chains).
1	S 40° W	17.50
2	N 45° W	22.25
3	N $36^{\circ}\frac{1}{4}$ E	31.25
4	North	13.50
5	(omitted)	(omitted)
6	S $8^{\circ}\frac{1}{2}$ W	34.25
7	West	32.50

4. From the notes given in Fig. 52, p. 103, and Fig. 161, p. 362, compute by the double meridian distance method the area of the traverse *ABCDEK*.

5. In the following traverse there are two mistakes. Find where they occur and determine their amounts.

Station.	Observed Bearing.	Deflection Angle.	Distance (Feet).	Calculated Bearings.	Remarks.
<i>A</i>	N 34° E	164° 14' R	240.2	N 34° 00' E	
<i>B</i>	S 73° $\frac{1}{2}$ E	62° 16' R	163.7		
<i>C</i>	S 10° $\frac{1}{2}$ W	84° 22' R	207.6		<i>CE</i> = 188.1
<i>D</i>	N 26° $\frac{1}{2}$ W	142° 49' R	273.1		<i>BCE</i> = 34° 14'
<i>E</i>	S 52° W	103° 41' L	147.4		<i>DEC</i> = 81° 25'

6. The following is a set of notes of an irregular boundary of a lot of land. It is desired to straighten this crooked boundary line by substituting a straight line running from *B* to the line *EF*. Find the bearing of the new boundary line and its length; also the distance along *EF* from point *E* to the point where the new line cuts *EF*.

Station.	Bearing.	Distance (Feet).
<i>A</i>	S 89° 14' E	373.62
<i>B</i>	N 13° 10' E	100.27
<i>C</i>	N 0° 17' W	91.26
<i>D</i>	N 27° 39' E	112.48
<i>E</i>	N 72° 12' W	346.07
<i>F</i>	S 5° 07' W etc.	272.42 etc.

7. (a) In the lot of land, *ABCD*, the lines *AB* and *DC* both have a bearing of N 23° E; the bearing of *AD* is due East; *AD* is 600 ft., *AB* is 272.7 ft., and *DC* is 484.6 ft. Find the length of a line *EF* parallel to *AB* which will cut off an area *ABFE* equal to half an acre. Also find the length of the lines *AE*, and *BF*. (b) What is the area of *EFCD*?

8. Given the notes of a traverse, which does not close, as follows: —

Station.	Deflection Angle.	
• 0		Find the length
6 + 40	6° 17' L	of a straight line
9 + 20	18° 43' L	from 0 to 20 + 64
14 + 55	12° 47' R	and the angle it
17 + 18	45° 24' L	makes with the
20 + 64	68° 06' R	line from 0 to 6
		+ 40.

9. Compute the area of the following traverse by coördinates

Station.	Deflection Angle.	Bearing.	Distance (Feet).
<i>A</i>	78° 10' 00" L	N 36° 14' 00" W	208.64
<i>B</i>	88° 28' 00" L		436.79
<i>C</i>	67° 02' 15" L		56.48
<i>D</i>	33° 39' 15" L		98.80
<i>E</i>	90° 00' 00" R		68.62
<i>F</i>	22° 51' 00" L		95.10
<i>G</i>	68° 50' 15" L		207.41
<i>H</i>	89° 48' 00" L		103.75
<i>I</i>	55° 00' 15" L		96.75
<i>J</i>	53° 49' 00" R		420.77

PART IV.

PLOTTING.

PART IV.

PLOTTING.

CHAPTER XIV.

DRAFTING INSTRUMENTS AND MATERIALS.

It is assumed in this section that the student is familiar with the ordinary drawing instruments such as the T-square, triangles, dividers, compasses, and scales, as well as with their use.

ENGINEERING DRAFTING INSTRUMENTS.

414. There are several drafting instruments which are used by engineers and surveyors but which are not so generally employed in other kinds of drafting work. The most common of these are briefly described in the following articles.

415. STRAIGHT-EDGE. — Engineering drawings are made with greater accuracy than much of the drafting work of other professions. In fact many engineering drawings are limited in precision only by the eyesight of the draftsman. It is evident, then, that to use a T-square which is run up and down the more or less uneven edge of a drawing board will not produce drawings of sufficient accuracy. For this reason in many classes of engineering work the edge of the drawing board is not relied upon. Furthermore, in most plots of surveying work the lines are not parallel or perpendicular to each other except by chance, but run at any angle which the notes require; and there is therefore not so much call for the use of a T-square as there is in architectural, machine, or structural drawings. All drawings are usually laid out starting from some straight line drawn on the paper by means of a straight-edge, which is simply a flat piece of steel or wood like the blade of a T-square. Steel straight-edges are more accurate and are more commonly used by engineering draftsmen than the wooden ones, the edges of which are likely to nick or warp and become untrue. They can be ob-

tained of almost any length and of any desired weight, the common length being about 3 feet.

416. ENGINEER'S SCALE. — Practically all engineering plans are made on a scale of 10, 20, 30, etc. feet to an inch. In the engineer's scale, therefore, the inch is divided into 10, 20, 30, etc. parts, instead of into eighths and sixteenths as in the architect's scale. Engineer's scales are made 3, 6, 12, 18, and 24 inches long. One form is the flat wooden rule with both edges beveled and a scale marked on each bevel. Some flat rules are beveled on both faces and on both edges of each face, thereby giving four scales on one rule. Still another very common form is the triangular scale, made of wood or metal, and having six different scales, one on each edge of the three faces. In such rules the scales are usually 20, 30, 40, 50, 60, and 80 ft. or 10, 20, 30, 40, 50, and 60 ft. to an inch. Scales are, however, often made having the inch divided into 100 parts, but in plotting a map which is on a scale of 100 ft. to an inch the work is probably more easily done by using a scale of 10, 20, or 50 divisions to an inch and estimating the fractional part of a division than by trying to plot with a 100-ft. scale which is so finely graduated as to be very hard to read without the aid of a magnifying glass. A 20-ft. or 50-ft. scale is more satisfactory for precision than a 10-ft. scale when it is desired to plot on a scale of 100 ft. to the inch. A plan on a 200-ft. scale is always plotted by using a 20-ft. scale, a 300-ft. plan by using a 30-ft. scale, etc.

A map covering considerable area, like the map of a state, for example, must be plotted to a very small scale, and this is usually given in the form of a ratio such as 1 to 500, 1 to 2500, etc., meaning that one unit on the map is $\frac{1}{500}$, $\frac{1}{2500}$, etc. of the corresponding distance on the ground; this is sometimes called the *natural* scale. For plotting such maps specially constructed scales with decimal subdivisions are used.

417. PROTRACTOR. — A *protractor* is a graduated arc made of metal, paper, celluloid, or horn, and is used in plotting angles. There are many varieties of protractor, most of them being either circular or semicircular.

418. Semicircular Protractor. — Probably the most common is the semicircular protractor which is usually divided into de-

degrees, half-degrees, and sometimes into quarter-degrees. Fig. 171 represents a semicircular protractor divided into degrees.

FIG. 171. SEMICIRCULAR PROTRACTOR.

In plotting an angle with this protractor the bottom line of the instrument is made to coincide with the line from which the angle is to be laid off, and the center of the protractor, point *C*, is made to coincide with the point on the line. On the outside of the arc a mark is made on the drawing at the desired reading. The protractor is then removed from the drawing and the line drawn on the plan.

FIG. 172. SEMICIRCULAR PROTRACTOR.

Instead of having the 0° and 180° of the protractor on its lower edge some instruments are made as shown in Fig. 172.

This form is claimed by some draftsmen to be more convenient, because in handling the protractor by placing the fingers on the base neither the graduations nor the line on the plan are covered by the hand.

419. Full-Circle Protractor. — The full-circle protractor is of use particularly in stadia work or in plotting any notes where azimuth angles of over 180° have been taken. For such work as stadia plotting an ordinary paper protractor 8 to 12 inches in diameter is sufficiently accurate, and, in fact, paper protractors of this size will yield more accurate results than the smaller metal ones.

420. Some of the metal protractors are provided with an arm and vernier attachment. These, while giving more precise results, require more time for manipulation, and a plain metal protractor with a diameter of, say, 8 inches will give sufficiently close results for all ordinary work. As a matter of fact a protractor with a vernier reading to minutes can be set much closer than the line can be drawn, and it is therefore a waste of time to attempt to lay off the angles on a drawing with any such accuracy. There is, however, a protractor of this type with a vernier reading to about 5 minutes which may be of use in precise plotting.

421. Three-Armed Protractor. — The three-armed protractor is used for plotting two angles which have been taken with an instrument (usually a sextant) between three known points, for the purpose of locating the position of the observer (the vertex of the two angles). The protractor has three arms, the beveled edges of which are radial lines. The middle arm is fixed at the 0° mark and the other two arms, which are movable, can be laid off at any desired angle from the fixed arm by means of the graduations on the circle, which number each way from the fixed arm. The two movable arms having been set at the desired angles and clamped, the protractor is laid on the plan and shifted about until each of the three known points, (which have already been plotted on the plan), lies on a beveled edge of one of the three arms of the protractor. When the protractor is in this position its center locates the point desired which is then marked by a needle point. Only one location of this center point can be obtained except in the case where the three known

points lie in the circumference of a circle which passes through the center.

422. There are several other types of protractor made, but the principle and use of all of them are much the same as those of the simple types which have been explained. It is well in purchasing a protractor to test it to see that the center point lies on a straight line between the 0° and 180° marks, that the edge of the protractor is the arc of a true circle, and that the graduations are uniform.

423. PANTOGRAPH. — This instrument is composed of several flat pieces of metal or wood joined in such a way as to form a parallelogram. One of the three points *A*, *B*, and *C*, (Fig. 173) is fixed and the other two movable. The remaining bear-

FIG. 173. THE PANTOGRAPH.

ing points are not essential except to support and steady the instrument. The two movable points are so attached to the instrument that they will trace out exactly similar figures. The instrument is used for copying a plan either to the same or to a different scale. There are several different forms of pantograph varying considerably in appearance, but they are all based on the same principle. The essential condition in their design is that all three points *A*, *B*, and *C*, must lie in a straight line and each point must be on one of three different sides (or sides produced) of a jointed parallelogram. Any one of the three points can be the fixed point. It is evident then that by changing the relative positions of these points, by moving them up or down the arms of the parallelogram, but always keeping the points on a

straight line, the scale of the copy can be made to bear any desired relation to the scale of the original drawing. These instruments are usually provided with scales marked on the arms indicating the proper settings for various reductions or enlargements. With a pantograph very accurate results cannot as a rule be obtained because there is lost motion in the several joints of the instrument. Some of the expensive metal pantographs, however, will give fairly good results.

424. PARALLEL RULER. — This is a beveled rule made of metal and mounted on two rollers of exactly the same diameter. It is used for drawing parallel lines. This instrument can be made to do accurate work, but it must be handled with a great deal of care to prevent the rollers from slipping. It is especially useful in drafting diagrams of graphical statics in connection with structural design, in drawing the parallel sides of buildings, section lining, blocking out for titles, and in drafting large titles which require mechanical lettering.

425. BEAM COMPASS. — This is an instrument used for drawing the arcs of circles whose radii are longer than can be set out with the ordinary compass drafting instrument. It is composed of a strip of wood or metal with two metal attachments which can be fastened to it. One of these attachments carries a needle point and the other, which is usually provided with a slow-motion screw for exact settings, carries a pencil or a pen. This instrument is particularly useful in laying out large rectangles such as are called for when surveys are plotted by coördinates (Art. 449, p. 401).

426. CONTOUR PEN. — This pen is constructed very much like an ordinary right-line ruling pen except that it has a metal shaft, running through the entire length of the holder, to which the pen is attached. The shaft revolves inside of the holder, and the pen is so shaped that it drags behind taking a position in the direction in which it is being moved. It is used for drawing irregular curved lines such as contours or shore lines. Not a little practice is required before one can use a pen of this type accurately. When skill in its use is once acquired, however, a plan can be easily made on which the contours all have a uniform weight of line giving a very satisfactory appearance. The

purpose of a contour line is to show the facts as to the surface, and this pen should not be used unless it is found by trial that it does the work in hand properly. Accuracy is more important than appearance.

427. PROPORTIONAL DIVIDERS. — Proportional dividers are substantially an ordinary pair of dividers with both legs prolonged through the pivot-point thereby forming another pair of legs above the pivot. The pivot is movable so that it can be pushed up and down in a slot in the legs and clamped in any desired position, thereby altering the relative lengths of the two pairs of legs. The sliding is accomplished in some dividers by a rack-and-pinion motion. When the pivot is in the middle position the legs are equal, and the space between the two points of one pair of legs is equal to the space between the other pair. There are marks on the legs showing the proper settings for the pivot so that the space between one pair of points will bear any desired ratio to the space between the other pair. The marks on the legs should not be accepted as correct, but should be tested by actual trial. One end of the proportional dividers is used to space off the distances from the original map and the other end used to plot that distance on the new map. Thus by means of this instrument a drawing can be enlarged or reduced to a definite scale without the use of the engineer's scale.

A drawing which is to be made two-thirds the size of the original can be readily reduced by scaling the distances from the original with a 20-ft. scale and plotting them on the new drawing by use of a 30-ft. scale. But when the reduction is some odd ratio which cannot be readily accomplished by means of the engineer's scale proportional dividers are very useful.

428. RAILROAD CURVES, FRENCH CURVES, FLEXIBLE CURVE, AND SPLINE. — For drawing arcs of curves of long radii, such as occur on railroad plans and on plans of curved streets, in city work, curves made of wood, hard rubber, celluloid, or metal are used; these come in sets of about one hundred, with radii varying from about 2 inches to 300 inches. The metal curves are the most common and are made with the inside and outside edges of the same radii both edges being beveled. When a pencil line is drawn the beveled edges may be used against the

paper, and when ink lines are drawn the curve can be turned over so that the beveled edges are up, thus preventing the ink from running in under the curve on the paper. Some curves for railroad work are made with a short straight edge tangent to the curve at one end and with the point where the curve begins marked by a line across it.

429. Irregular curves, called *French Curves*, are of a variety of shapes. They are made of wood, hard rubber, and celluloid, and are used to guide the pencil or pen in tracing out irregular curved lines on the map.

430. A *Flexible Curve* consists of a strip of rubber fastened to a flexible metal back. This curve can be twisted to conform to any irregular curved line on the map and can then be used as a guide against which the pencil or pen is held in tracing out the curve.

431. A *Spline* is a long thin flexible piece of wood, hard rubber, celluloid, or metal which can be bent so as to conform to a curve. It is usually held in position by specially designed weights with light metal arms which fit into a thin groove in the top edge of the spline. This instrument is used by naval architects for drawing long flat irregular curves such as occur in ship designs. In engineering drafting it is used in drawing the lines of arches, which frequently are not circular.

DRAWING PAPERS.

432. The drawing papers used by surveyors may be divided into four general classes; (1) those used for plotting plans, (2) tracing paper or tracing cloth which is used for copying drawings, (3) cross-section and profile papers, and (4) process papers.

433. DRAWING PAPER FOR PLANS.*—There are numerous grades of drawing paper ranging from very cheap "detail" to heavy paper mounted on cloth, called "mounted paper." For rough plots which are to be copied later or which are for temporary use only, a manilla detail paper is frequently used; but where the drawing is to be of a more permanent character a heavy white or manilla paper is used. Still more permanent

* See Appendix C for description of how to mount drawing paper on cloth.

plans, such as the plan of a survey of a city, should be plotted on heavy mounted paper. There is generally a right and a wrong side to all papers, which can be distinguished by the "water-mark"; this will read direct when the right side of the paper is toward the observer. A paper to be satisfactory for use should have a surface not too porous to take ink nicely, and of a fiber such that after scratching with a knife or rubbing with an ink eraser, the surface will still take ink effectively. No paper, however, after scratching can be expected to take bottle red ink, which permeates the fiber with extraordinary ease.

434. TRACING PAPER AND TRACING CLOTH. — In making copies of drawings, a thin transparent paper called *tracing paper* is often used. It is not tough enough to withstand rough handling and is used only for drawings of a temporary character. There are, however, certain kinds of transparent bond paper in use which will withstand considerable hard usage.

435. For more permanent drawings a *tracing cloth* is used, made of a very uniform quality of linen coated with a preparation to render it transparent. Most tracing cloth as it comes from the manufacturer will not readily take the ink, and it is necessary to rub powdered chalk or talc powder over the entire surface of the cloth before inking the drawing. After the surface chalk is brushed off, the tracing cloth is ready for use. Tracing linen generally has one side glazed and the other dull. Pencil lines can be drawn on the rough side, but the smooth side will not take even a very soft pencil; either side may be used for ink drawings. Some draftsmen prefer to use the glazed side but the dull side is more commonly used. A tracing inked on the glazed side may be tinted on the dull side either by crayons or by a wash; the latter will cockle the cloth unless it is put on quite "dry." It is easier to erase from the glazed than from the dull side, but the dull side will stand more erasing,* and gives more uniform lines.

* Erasure of ink lines from a tracing, as well as from any drawing paper, is a delicate undertaking. Success will result if the following suggestions are carefully observed: — with a smooth sharp knife pick off the ink from the paper; this can be done almost without touching the paper. When practically all of the ink is off, rub the line with a pencil eraser. This will take off the rest of the line except

In making a tracing of another tracing it will be found that the lines can be more readily seen if a white paper is put under the lower tracing. It frequently happens that it is necessary to make a tracing of a blue-print. The white lines of the blue-print are not easily seen through the tracing linen. An arrangement which will assist greatly in such work is to have a piece of plate glass set into the top at one end of a drawing table in such a way that it forms part of the top of the table. The blue-print is placed over this glass and the light shining through from the under side of this glass and through the blue-print will make the white lines easily visible for copying.

It is common practice, after a survey is made and before or during the computation of it, to plot the field notes accurately on detail paper and later to copy the plot on tracing cloth, which is the final drawing of the survey.

From these tracing drawings any number of process prints can be made (Art. 438), the tracing taking the place of the negative used in photographic printing.

436. CROSS-SECTION, AND PROFILE PAPERS. — Paper divided into square inches which, in turn, are divided into small subdivisions is used to plot cross-sections of earthwork and the like. The inch squares are usually divided into $\frac{1}{8}$ ", $\frac{1}{16}$ ", $\frac{1}{32}$ ", or $\frac{1}{64}$ ". Cross-section paper can also be obtained divided according to the metric system, or with logarithmic divisions. Cross-section paper usually comes in sheets.

437. Profile Paper which, as the name implies, is used for plotting profiles comes in rolls of 10 yds. or more. The vertical divisions are usually much smaller than the horizontal divisions, which makes it easier to plot the elevations accurately. The horizontal distances to be plotted occur mostly at full sta-

perhaps a few specks of ink which can readily be removed by a sharp knife. This method of erasing takes more time than the ordinary method of rubbing with an ink eraser until the line has disappeared, but it leaves the paper in much better condition to take another line. It is impossible to obtain good results by this method unless the knife has an edge which is both smooth and sharp. Where the surface of the tracing cloth has been damaged the application of a thin coating of collodion on the damaged portion will produce a surface which will take the ink.

tion points, which are represented on the profile by the vertical rulings on the paper.

Both the cross-section and the profile papers come in colors, (usually red, green, blue, orange, or burnt sienna) so that a black or a red ink line (the two most commonly used) will show up distinctly on the paper. These papers can be obtained also of very thin transparent material or in tracing cloth form, suitable for use in making process prints. Profile papers usually come in long rolls 20 inches wide.

438. PROCESS PAPERS. — Blue-Prints. — The most common process paper used in drafting offices is blue-print paper. It is a white paper coated on one side with a solution which is sensitive to light. After the solution is applied, the paper is dried and then rolled and sealed up for the market in light-proof rolls of 10 yds. or more. Fresh blue-print paper has a greenish-yellow color. The process of coating the paper and the general handling of the blue-print business is so well advanced and the price of the prepared paper is so low that surveyors now-a-days seldom coat their own paper. The process is a very simple one, however, and in emergencies, when commercial blue-print paper cannot be obtained, it may be very useful to know how to prepare it. A good formula for the solution is given below.

Make the following two solutions separately (in the light if desirable) and mix, **in subdued light or in a dark room**, equal parts of each of them.

Solution (1)

Citrate of Iron and Ammonia, 1 part (by weight)
Water, 5 parts (“ “ ”)

Solution (2)

Red Prussiate of Potash (re-crystalized), 1 part (by weight)
Water, 5 parts (“ “ ”)

The mixed solution is applied to the paper by means of a camel's hair brush or a sponge; this is done in a dark room or in subdued light. The paper is coated by passing the sponge lightly over the surface three or four times, first lengthwise of the paper and then crosswise, giving the paper as dry a coating

as possible consistent with having an even coating; it is then hung up to dry. The above coating will require about 5 minutes exposure in bright sunlight; for quick printing paper, use a larger proportion of citrate of iron and ammonia.

The blue-print of a plan is generally made in a printing frame, which is merely a rectangular frame holding a piece of heavy glass, with a back to the frame which can be lifted from the glass. This back is padded so as to fit tight against the glass when the back is clamped into position. The process of taking a print is, briefly, to expose the tracing, with the blue-print paper under it, to the sunlight a proper length of time and then remove the blue-print paper and wash it in water.

439. In detail, the process is as follows. First, turn the printing-frame over so that the glass is on the bottom, and remove the back of the frame. Then, after the tracing cloth has been rolled, if necessary, so that it will lie flat, place it **with its face against the glass**. Place the blue-print paper, which has been cut to the proper size, on top of the tracing with the **sensitized side of the paper next to the tracing**. The back of the frame is then clamped into position and the frame turned over so that the glass is up. It should then be examined to see that the tracing has been put into the frame with its ink lines against the glass, that the blue-print paper is under the entire tracing, and that there are no wrinkles in the tracing. All of the process to this stage should be done in subdued light, usually in a room with the shades drawn to keep out most of the sunlight.

The frame is then moved out into the direct sunlight, placed as nearly as may be at right angles to the rays of sunlight, and left there a proper length of time, which will depend upon the sensitiveness of the coating of the paper and the intensity of the light. Some blue-print papers will print in 20 seconds, others require 5 or 6 minutes in direct sunlight. In purchasing, then, it is necessary to ascertain from the dealer the "speed" of the paper and govern the exposure accordingly. Blue-prints can be made in cloudy weather as well as when the sun is visible, the only difference being that it requires a much longer time for the exposure. In all cases where the time of exposure is doubtful the following simple test may be applied. Instead of taking a

print of the entire tracing the first time, use only a small piece of the blue-print paper and put it in the frame as explained above and expose it a given time. Take it out and wash it, and from this test judge the length of exposure necessary to give the print of the entire drawing. An under-exposed print, after it has been washed, will be light blue in color with white lines; an over-exposed print will be dark blue with bluish-white lines. The result desired is a **dark or medium blue background with white lines**. It should be borne in mind, in judging the results, that all prints become a little darker when they are dry.

In washing the print it should be entirely immersed in clear water at first; care should be taken that no part of the print is left dry. It should be washed by moving it back and forth in the water or by pouring water over it until the greenish solution is entirely washed off its face. The print should be left in the water for 10 to 20 minutes, then it is hung up to dry. It will dry more quickly if hung so that one corner is lower than the others. It should not be hung where the sun will shine on it as the sunlight will fade it.

In taking prints great care must be exercised **not to get the tracing wet**. When the prints are being washed **the tracing should always be put in a safe place where the water will not spatter on it** and it should never be handled with moist hands. It is practically impossible to eradicate the effect of a drop of water or even the marks made by damp fingers on tracing cloth; it is sure to show in every subsequent print which is taken from the tracing.

440. Blue-print cloth is prepared in the same manner as the blue-print paper. Its advantage over the paper lies solely in the fact that it does not shrink as badly and is much more durable. Prints which are to be used on construction work where they are sure to get rough usage are sometimes made on cloth.

441. Vandyke Solar Paper. — There has always been a call for a sensitive paper which will give positive prints, — a black, a brown, or a blue line on a white background. Such effect was secured by the old so-called "black print process," but its operation was not altogether simple and good results were not reason-

ably sure. The Vandyke paper has apparently solved this difficulty, and in addition affords other advantages which the old "black process" paper did not possess.

Vandyke paper is a sensitized paper which is printed in the same way as a blue-print, except that the tracing is put into the frame so that the ink lines will be **against** the Vandyke paper. The exposure is about 5 minutes in direct sunlight or, more definitely, until the portion of the Vandyke paper which protrudes beyond the tracing is a rich dark tan color. Fresh Vandyke paper is light yellow in color. The print is washed for about 5 minutes in clear water (where it grows lighter in color) and then it is put into a solution consisting of about one-half ounce of fixing salt (hyposulphite of soda) to one quart of water, where it turns dark brown. It is left in the fixing bath about 5 minutes, after which the print is again washed in water for 20 to 30 minutes and then hung up to dry. The fixing solution may be applied with a sponge or brush if only a few Vandykes are being made, but it is better to immerse them in a tank containing the solution.

After the Vandyke print is washed the body is dark brown in color while the lines are white. This is not the final print to be sent out; it is simply the *negative*.

This Vandyke print is then put into the printing-frame in place of the tracing, the **face** of the Vandyke being **next** to the sensitive side of the process paper, and from it as many prints as are desired are made on blue-print paper or on any kind of sensitized paper desired. These blue-prints made from Vandykes have a white background while the lines of the drawing appear in deep blue lines, for in this case the rays of the sun act only through the white parts of the Vandyke (the lines), whereas in making an ordinary blue-print from a tracing the sun's rays act on the paper through all parts of the tracing cloth **except** where the lines appear. Where brown lines on a white background are desired, the print is made by using a sensitized sheet of Vandyke paper, in place of the blue-print paper.

One of the advantages of this process is that, as soon as a Vandyke has been made from the tracing, the tracing can be filed away and kept in excellent condition, the Vandyke being used in making all prints.

Another advantage in the use of the blue-prints which have been made by this process is that any additions made in pencil or ink show clearly on the white background of the print which is not true of the ordinary blue-print, on which corrections must be made with a bleaching fluid or water-color.

442. Electrical Printing Frames. — The uncertainty of the sunlight for making prints has brought forward a printing frame in which an artificial light is used.

One form of electrical printing frame is an apparatus consisting of a hollow glass cylinder, formed of two sections of glass, and resting on a circular base which is rotated by clock work. An electric light is suspended in the center line of the cylinder where it travels up and down by means of a clock work attachment.

The tracing and paper are wrapped around the outer surface of the glass where they are tightly held against the glass by a canvas which is wound around the cylinder by means of a vertical roller operated by a handwheel. The cylinder can be rotated at any desired speed and the light which travels up and down the axis of the cylinder can be moved through any desired distance or at any desired speed. These motions are all made automatically when the apparatus is once adjusted.

In another type of electrical machine several horizontal rollers are provided, with the light so arranged that as the tracing and blue-print paper passes from one roller to another the exposure is made. The speed of the machine is controllable and the length of the tracing that can be printed is limited only by the length of the roll of blue-print paper. With this machine, then, long plans or profiles can be printed without the necessity of frequent splicing which is required with other types of printing frame; furthermore the color of the print is also uniform throughout. The machine is driven by an electric motor. There are several machines of this general type on the market; some of them are provided with an apparatus for washing the prints as fast as they come from the machine.

443. INKS AND WATER-COLORS. — Bottled ink, which is prepared in various colors, is used extensively on engineering drawings. The so-called "waterproof" inks differ from other

inks in that a water-color wash can be put over the lines without causing them to "run." Bottled inks are satisfactory for most drawings, but when very sharp and fine hair-lines are required it is well to use the stick india ink. This is made by grinding the ink together with a little water in a saucer made for this purpose, until the ink is thick and black enough to be used. If the ink becomes dry it can be restored to as good condition as when first ground by adding water, a drop or two at a time, and rubbing it with a piece of cork or a pestle; if the water is added too rapidly the ink will flake.

While the bottled black inks are fairly well prepared, the red inks are very unsatisfactory. They will sometimes run on paper where only very slight erasures have been made; in fact, on some of the cheaper papers red ink will always run. For tracing purposes red ink is wholly unsatisfactory, as it is impossible to obtain a good reproduction of a red ink line by any of the process prints. Where red lines are needed the use of *scarlet vermilion water-color* will be found to give not only a brilliant red line on the tracing, but also "body" enough in the color so that the lines will print fully as well as the black ink lines. Scarlet vermilion water-color will give much better lines on any paper than the bottled red inks. Only enough water should be used to make the water-color flow well in the pen. Other water-colors are used in the place of the bottled colored inks, such as *Prussian blue* instead of bottled blue ink, or *burnt sienna* instead of brown ink, and these give much better results.

It is frequently necessary on blue-prints to represent additions in white, red, or yellow. A white line can easily be put on by using *Chinese white* water-color; but sometimes a bleaching fluid is used which bleaches out the blue leaving the white paper visible. The best color for a red line on blue-prints is scarlet vermilion water-color; and for a yellow line none of the ordinary yellow water-colors gives as brilliant lines as Schoenfeld & Co.'s *light chrome yellow*.

For tinting drawings water-colors and dilute inks are used. Effective tinting may be done on tracings by using colored pencils on the rough side of the linen.

CHAPTER XV.

METHODS OF PLOTTING.*

444. LAYING OUT A PLAN. — Laying out a plan requires careful work. If a good-looking plan is to be obtained this part of the work must be done with not a little judgment. Besides the plan of the survey or property the drawing must have a title, and sometimes notes and a needle to show the direction of the meridian. These must all be arranged so that the entire drawing when completed will have a symmetrical appearance. Often the plot is of such awkward shape that it is very difficult to lay out the drawing so that it will look well, and the draftsman's artistic instincts are taxed to the utmost to produce a satisfactory result.

445. Scale. — In many cases the scale of the plan as well as the general arrangement of its parts must be chosen by the engineer. Surveys of considerable extent which do not contain a great many details, such, for example, as the preliminary survey for a railroad, may be drawn to a scale of 400 ft. to an inch. A plan of a large piece of woodland or a topographical map of a section of a town may be represented on a scale of from 100 ft. to 400 ft. to an inch. A plan of a city lot for a deed is represented on a 20-ft. to 80-ft. scale; and city streets, such as sewer plans and the like, are frequently drawn to a scale of 20 ft. to 40 ft. to an inch. Sometimes on plans of construction work drawings of different scale are made on the same sheet. The drawing for a conduit, for example, may be represented by a general plan on a scale of 80 ft. to an inch, while on the same sheet the conduit may be shown in section on a scale of 4 ft. to an inch.

The field maps of the U. S. Coast and Geodetic Survey are usually plotted on a scale of $\frac{1}{100000}$, but some special maps are made on scales as large as $\frac{1}{50000}$. The field maps of the U. S. Geological Survey are mostly plotted to a scale of $\frac{1}{300000}$ and reduced on the lithograph sheets to $\frac{1}{500000}$ or $\frac{1}{1000000}$.

* For a brief description of different projections for maps of large areas, such as states or counties, see Volume II, Chapter X.

These remarks in regard to scales are not to be considered in any sense as hard and fast rules to govern all conditions. They are suggested simply to give some idea of the existing practice in this matter.

METHODS OF PLOTTING TRAVERSES.

446. PLOTTING BY PROTRACTOR AND SCALE. — The most common method of plotting angles is by use of the protractor (Art. 417, p. 382), and of plotting distances, by use of the engineer's scale. Every traverse consists of a series of straight lines and angles, which can be plotted by a protractor in the following manner. First, the survey to be mapped should be sketched out roughly to scale, in order to ascertain its extent and shape so as to decide the size of paper necessary for any given scale of drawing and to determine its general position on the sheet, which will fix the direction of the first line of the traverse, to be used as a starting line for the entire drawing. This having been done, the first line is drawn in the proper place on the paper, its length is scaled off by using the proper scale, and its two extremities accurately marked by pencil dots or by means of a needle point, and surrounded by a light penciled circle. The line should be drawn so that it will extend beyond the next angle point a distance greater than the radius of the protractor, this extension of line being of use in the manipulation of the protractor.

The protractor is placed so that its center is exactly on the second angle point and so that both the 0° and 180° marks of the protractor exactly coincide with the line. The traverse angle taken from the field notes is plotted, the protractor removed, the line drawn, and the length of the second course carefully scaled. Then the protractor is placed along this new line and opposite the third point, the angle at that point is laid off, the next line drawn, and the distance scaled. By this process the entire traverse is plotted.

447. Checks. — On all plotting work, just as on all field-work and computations, frequent checks should be applied to insure accuracy.

If the traverse is a closed traverse the plot, of course, should close on the paper.* If it does not and the error of closure is in a direction parallel to any one of the lines, there is probably a mistake in plotting the length of that line. If there is no indication of this sort the mistake may be either in scaling, in laying off the angles, or in both. In such a case the entire plot should be checked unless there is some reason to think that a certain line may have been laid off at the wrong angle, in which event that questionable angle should be replotted. The bearings of all the lines of the traverse can be computed with reference to the magnetic or to any assumed meridian; any line can be produced to meet the meridian line, and this angle measured and checked. Similarly, the bearing of the last line of a traverse which does not close can be computed and the angle the last line makes with the meridian measured. If it checks the computed angle it is evident that no error has been made in the angles unless mistakes were made that exactly balance each other, which is not probable. In this way, by "cutting into" the drawing here and there, the angular error, if there is one, can be quickly "run down," without laying out all of the angles again and so possibly repeating the mistake that was originally made. The angles measured in applying this check have different values from the ones first laid out, and the chance of repeating the original mistake is thereby eliminated. If no error is found to exist in the angles, the distances should next be checked. This can be done in two ways, and in some drawings both of these checks should be applied.

First, scale each line separately setting down the results independently upon a sheet of paper. After these are all recorded (and not before), compare the lengths with the lengths of lines as taken from the field notes. No error should be allowed to pass if it is large enough to be readily plotted by the use of the scale.

* Instead of plotting every line of the traverse from its preceding line and returning, in the case of a closed traverse, to the other end of the starting line, it may be well to plot half the traverse from one end of the starting line and the other half from the other end; the check will then come at a point about half-way around the traverse. The advantage of this method lies in the fact that accumulative errors are to some extent avoided since they are carried through only half as many courses.

Second, take a long straight piece of paper, lay this on the drawing, and mark off the length of the first line on the edge of the paper; then mark off the length of the second line starting from the mark which denotes the end of the first line, and proceed in a similar way to the end of the traverse. Apply the scale to the strip of paper and read the station of each mark; record each of these independently and afterwards compare them with the field notes. The entire length of line should check within a reasonable amount depending upon the scale; the allowable error can easily be determined by the principle explained in Art. 23, p. 14.

By checking angles and distances by the above methods errors of any consequence can be avoided; in any case a draftsman should not allow a drawing to leave his hands which has not been properly checked and known to be correct.

When the traverse is not closed, such checks as have been described above must **always** be applied; otherwise there is no assurance whatever that the plan is correct. It is especially necessary to check the bearings of lines frequently, so that the accumulation of small errors may not become appreciable.

448. Protractor and T-Square. — While the ordinary T-square is not much used in plotting engineering plans, there are some occasions where it is convenient to use it. Where a traverse has been run by bearings or by deflection angles the T-square with a shifting head can be conveniently used in connection with a protractor for plotting the angles by bearings.

The paper is fastened to a drawing board having a metal edge, which insures one straight edge to the board. A meridian line is drawn on the paper, and the shifting head of the T-square is fastened so that the blade coincides with the meridian line. Then as the T-square is slid up and down the edge of the drawing board its blade always takes a direction parallel to the meridian. By means of the protractor shown in Fig. 172 the bearing of each line can be readily laid off or checked as illustrated by Fig. 174 and the distances laid off with the scale. In order to secure a satisfactory check, the deflection angles should be laid off directly from the previous line, and the bearings checked by means of the T-square and protractor.

It is evident that the bearings of the lines may be computed just as well from any assumed meridian as from the magnetic or true meridian; and that the drawing can be fastened to the board

FIG. 174. LAYING OFF BEARINGS BY USE OF T-SQUARE AND PROTRACTOR.

in such a way that the T-square can be conveniently used. This method is especially applicable to compass surveys as it obviates the necessity of drawing a new meridian line through each angle point.

This method can be easily applied also as a means of checking any of the angles of a traverse which have been plotted by any of the ordinary methods.

449. PLOTTING BY RECTANGULAR COÖRDINATES.— In plotting by this system all points in the traverse are referred to a pair of coördinate axes. For convenience these axes are often the same as those used in calculating the area enclosed by the traverse. The advantages of this method are, (1) that all measurements are made by means of the scale only and (2) that the plotting may be readily checked.

To plot a survey of a field by rectangular coördinates, first calculate the *total latitude* and the *total departure*, that is, the ordinate and the abscissa, of each point in the survey. If the meridian through the most westerly point and the perpendicular through the most southerly point are chosen as the axes negative

signs in the coördinates will be avoided. The coördinates of the transit points are computed by beginning with the most westerly point, whose total departure is zero, and adding successively the departure of each of the courses around the traverse. *East* departures are called *positive* and *West* departures *negative*. The total departure of the starting point as computed from that of the preceding point will be zero if no mistake is made in the computations. The total latitudes may be computed in a similar manner beginning, preferably, with the most southerly point as zero.

450. For plotting the points on the plan, a convenient method of procedure is to construct a rectangle whose height equals the difference in latitude of the most northerly and the most southerly points and whose width equals the difference in departure of the most westerly and the most easterly points. If the most westerly and the most southerly points are taken as zero then the greatest ordinate and the greatest abscissa give the dimensions of the rectangle. The right angles should be laid off either by the use of a reliable straight-edge and a triangle or by the beam compass.

451. The better method, however, is to construct the perpendiculars by means of a straight-edge and a triangle. It is

FIG. 175. ERECTING A PERPENDICULAR WITH A STRAIGHT-EDGE AND AN INACCURATE TRIANGLE.

not at all necessary, although it is always desirable, that the triangle shall be accurate. It should be used in the following manner. It is first placed against the straight-edge, as shown by the full lines in Fig. 175, and a point *A*, marked on the paper. Point *C* is also marked opposite a certain definite part of the triangle. Then the triangle is reversed to the dotted position and brought so that its edge coincides with point *A*, and then point *B* is marked opposite point *C*, as nearly as can be judged. A point *D* is plotted midway between *B* and *C* and the line *AD* is then drawn which is perpendicular to the straight-edge. If the triangle is accurate point *B* will fall on point *C*, so that this is a method of testing the accuracy of the right angle of any triangle. If it is found to be inaccurate it should be sent to an instrument maker and be "trued up." A few cents spent in keeping drafting instruments in shape will save hours of time trying to locate small errors, which are often due to the inaccuracy of the instruments used.

If the compass is used the right angle may be laid off by geometric construction. On account of the difficulty of judging the points of intersection of the arcs, very careful work is required to obtain good results with the compass.

Since the accuracy of all of the subsequent work of a coördinate plot depends upon the accuracy with which the rectangle is constructed, great care should be taken to check this part of the work. The opposite sides of the rectangle should be equal and the two diagonals should be equal, and these conditions should be tested by scaling or with a beam compass before continuing with the plot.

452. After the rectangle has been constructed, all points in the survey can be plotted by use of the scale and straight-edge. To plot any point, lay off its total latitude on both the easterly and the westerly of the two meridian lines of the rectangle, beginning at the southerly line of the rectangle. Draw a line through both of these points by means of a straight-edge.*

* Accurate work, of course, cannot be obtained with a straight-edge that is not true. A straight-edge can easily be tested by drawing a fine pencil line on the paper along one edge of the straight-edge; then turn the straight-edge over on its other side, fit the same edge to the two ends of the pencil line, and see if the edge coincides with the line.

Then lay off along this line the total departure, beginning at the westerly side of the rectangle, thus obtaining the desired position of the point.

The computations of the total latitudes and departures and the method of plotting a traverse by the coördinate method are shown in Fig. 176. This is the survey which is shown in the

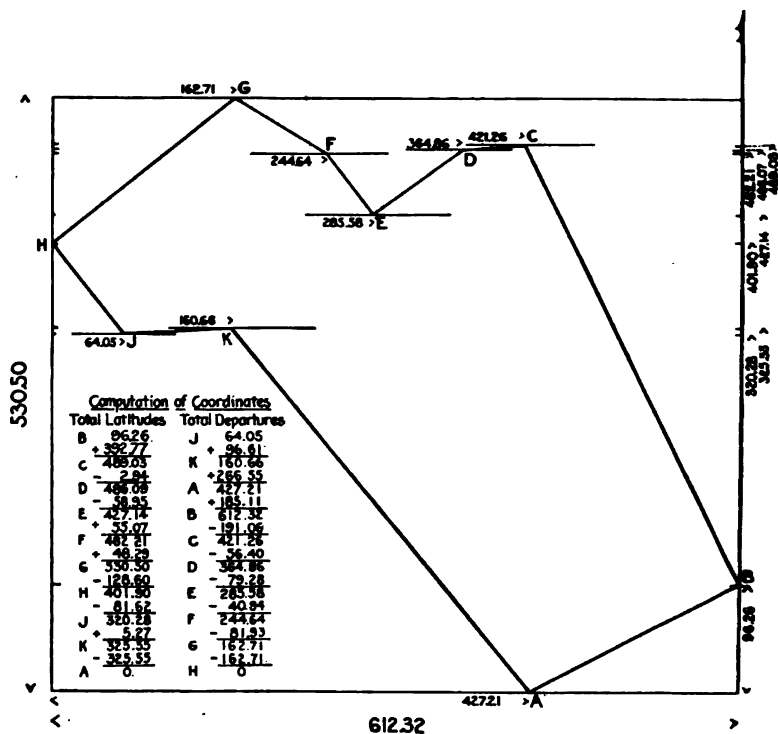

FIG. 176. COMPUTATIONS AND PLOTTING BY RECTANGULAR COÖRDINATES.

calculations in Fig. 161, p. 362, and in the form of notes in Fig. 52, p. 103.

453. Plotting by rectangular coördinates is the most accurate of all the methods usually employed. It is not very often applied, however, to traverses which do not close, as there is seldom any other use for the coördinates of such a traverse, and the

labor of computing them for this purpose alone is hardly warranted. For such traverses, therefore, either the protractor and scale, the Tangent Method, or the Chord Method (which are explained in the following articles) may be employed. But for plans of a closed traverse, where the latitudes and departures have been computed in connection with calculating its area, this coördinate system of plotting is frequently used.

454. Checks. — When the transit points have been plotted, the scale distance between consecutive points should equal the distance measured in the field. It sometimes happens that some of the transit lines run so nearly parallel to one of the axes that the distances will scale the right amount even though a mistake has been made in laying off one of the coördinates. In such a case any appreciable error can be detected by testing the bearings of the lines by means of a protractor. These two tests, together with the scaled distances of any cut-off lines which may have been measured in the field, (Art. 145, p. 109), form a good check on the accuracy of the plotting. Since all of the points are plotted independently errors cannot accumulate. If it is found that any scaled distance fails to check with the measured distance it is probable that one of the two adjacent lines will also fail to check and that the point common to the two erroneous lines is in the wrong position.

It should be remembered that everything depends upon the accuracy of the rectangle and that nothing should be plotted until it is certain that the right-angles have been accurately laid off.

455. PLOTTING BY TANGENTS. — The traverse should first be plotted approximately on some convenient small scale by use of the protractor and scale, to ascertain its extent and shape. The importance of this little plot is often overlooked, with the result that when the plan is completed it is found to be too close to one edge of the paper or otherwise awkwardly located on the sheet. It takes only a few moments to draw such a sketch, and unless the draftsman is sure of the shape and extent of the plot he should always determine it in some such manner before the plan is started.

The directions of all the lines are referred to some meridian

and the bearings determined with an accuracy consistent with the measured angles. From the auxiliary plot it can be decided where to start the first course of the traverse on the paper and in what direction to draw the meridian, so that the lines of the completed traverse will be well balanced with the edges of the sheet, and so that the needle will be pointing, in a general way, toward the top of the drawing rather than toward the bottom.

The bearing of the first line is plotted as follows (Fig. 177).

FIG. 177. PLOTTING BY TANGENT OFFSETS.

Lay off on the meridian line a length Aa of at least 10 inches and erect a perpendicular at a on the right-hand side of the meridian if the bearing of the first course is east, and on the left-hand side if it is west. Look up in the table of natural functions the tangent of the bearing of the first course and scale off this distance ab on the perpendicular.* Draw Ab which is

* These distances and also the 10-inch base-lines are all laid off by use of the engineer's scale. By using the 10-ft. or 100-ft. scale the tangents can be laid off without any computation, whereas with the other scales the tangent must be multiplied by some number, e.g., by 2 if the 20-ft. scale is used, by 3 if the 30-ft. scale is used, etc., taking care in the pointing off.

If it is deemed unnecessary to use a base as long as 10 inches, one can be laid off at the "10" mark on any engineer's scale and the tangent distances laid off by using the same scale, e.g., if a 20-ft. scale is used the "10" mark will give a base-line 5 inches long.

the direction of the first course. On this line scale off AB , the length of the first course. On this line produced lay off Bg equal to 10 inches and erect a perpendicular, scaling off on the perpendicular the length gd equal to the tangent of the **deflection angle** at B . This determines the direction of BC from the first course. The remaining lines of the traverse are plotted in the same manner, using each time the deflection angle.

456. Checks. — Unless the survey is a closed traverse checks must be occasionally applied. Every third or fourth course should be checked by finding the angle between it and the meridian line. This angle should be found by the same method (tangent offset method) and by using a base of 10 inches as in plotting the angles. In checking the course De , for example, a meridian is drawn through D parallel to Aa , De is scaled off 10 inches, and a perpendicular ef erected. The distance ef is scaled and from the table of tangents the angle fDe is obtained. If the angle that the course makes with the meridian line disagrees with the calculated bearing of that course by any considerable amount, say, 10 minutes of angle or more, the previous courses should be replotted. If the error is less than 10 minutes the course which is being checked should be drawn in the correct direction so that even the slight error discovered may not be carried further along in the plot. Then after the plotting has proceeded for three or four more courses the check is again applied.

The bearings of the lines can be checked by use of the protractor and this will detect errors of any considerable size, but this method will not disclose any small errors; moreover, if it is desired to have the plot when completed as accurate as could be expected from the precise method employed, it is entirely inconsistent to check by use of a method which is far less accurate than the one used in making the plot. For this reason the checks on the direction of the lines are applied with the same care and by the same method as was used in the original layout of the angles.

Occasionally it is more convenient to plot the complement of an angle rather than the angle itself, as was done in plotting the line EF . In this case the right angle erected at E must be laid

off with great care, preferably by the method explained in Art. 451, p. 402.

It is evident that the direction of each course could have been plotted by drawing a meridian line through the transit points and by laying off the **bearings** by the tangent method. But if such a method were used there would be no single check applied that would check all the previous courses, which is an important feature of the method explained above.

If the traverse is not closed the lengths of the lines of the traverse should **always** be checked by the methods explained in Art. 447, p. 398.

457. PLOTTING BY CHORDS.— This method, which is employed by many draftsmen in plotting traverse lines, is fairly good although probably not so accurate as the Coördinate or as convenient as the Tangent Methods.

Fig. 178 represents the traverse *ABCDEF* which has been

FIG. 178. PLOTTING BY CHORDS.

plotted by chords. It is the same traverse that is shown in Fig. 177.

On the meridian line the distance *Aa* is scaled off equal to 10 inches and the arc *ab* swung from *A* as a center by use of the ordinary pencil compass. Then from a table of chords * the

* Tables of chords can be found in Trautwine's "Civil Engineer's Pocket Book," published by John Wiley & Sons, New York.

length of the chord ab is found for the angle aAb . The point b is sometimes located by setting the dividers at the distance ab and with a as a center intersecting the arc ab at b ; but the more accurate method is to scale from point a the chord distance and mark the point b on the arc. Then the line Ab is drawn and AB scaled off on it. With B as a center the arc gd is drawn and the chord gd , corresponding to the deflection angle at B , is scaled off. Bd is then drawn and BC scaled off on it. In the same way the entire traverse is plotted.

458. Use of the Sine. — It is evident that the chord

$$ab = 2 \times 10 \times \sin \frac{A}{2};$$

hence, if a table of chords is not available, a table of sines (always easily obtainable) can be used. The sine of half the angle can be taken from the tables and multiplied by 20 mentally. Some draftsmen use the table of sines and a radius of 5 inches to avoid the multiplication. This is not recommended because a base of 5 inches is not long enough to insure a very accurate drawing. The necessity of multiplying by 2 can very easily be done away with by laying off the radius with a 20 ft. scale and scaling off the sine of the angle with a 10-ft. scale.

With dividers of the ordinary size it is impossible to lay out an arc with a 10-inch radius. In such a case either beam compasses must be used or the radius employed must be shorter, so short, in fact, that it will frequently be better to resort to the Tangent Method.

459. Checks. — Since this method is usually applied to traverses which do not close it is desirable to check every fourth or fifth course so that a mistake will not be carried too far before it is discovered and thereby cause a waste of time. In Fig. 178 it is desired to check the calculated bearing of De . The meridian Df is drawn through D parallel to Aa , the arc fe is swung with D as a center and with a radius of 10 inches, and the chord ef is scaled. From the table of chords (or sines) the angle fDe (the bearing) can be found. It should agree reasonably well with the calculated bearing. The degree of precision to be expected when plotting by chords is a little less than

that suggested for the Tangent Method in Art. 455, unless the beam compass is used. The Tangent Method, especially if the right angles are laid off by reversing the triangle, gives more accurate results than the Chord Method, for the use of the ordinary compass in the Chord Method is a fruitful source of error unless it is handled with the utmost care.

METHOD OF PLOTTING DETAILS.

460. BUILDINGS, FENCES, STREAMS, ETC. — The previous articles have dealt with the plotting of the traverse lines only, and these in many cases form merely the skeleton of the final plan. In the field the details of the survey are located from the transit line; and, in a similar manner, the details are located on the plan from the traverse line which has already been plotted.

Buildings, fences, shore-lines, streams, etc. are all plotted by means of the scale for distances and the protractor for the angles. Often a smaller protractor is used for this sort of work than for the traverse lines. This is permissible, for the lines which locate the details are usually short in comparison with the traverse lines and the resulting error is small in any case; furthermore any slight error in the location of a detail will not as a rule affect the rest of the drawing, whereas an error in a transit line will, of course, have an effect on all of the rest of the drawing. The plotting of buildings has been taken up in connection with their location. (See Chapter VI.)

In plotting a set of notes where several angles have been taken at one point, such as in stadia surveying, it is well to plot all of the angles first, marking them by number or by their value, and then to plot the distances with the scale.

461. CONTOURS. — Where contours are located by the cross-section method (Art. 304, p. 278), this cross-section system is laid out in soft penciled lines on the drawing. The elevations which were taken are written at their respective points on the plan and then the contours desired are sketched. The ground is assumed to slope uniformly between adjacent elevations, and, by interpolation between these points, the location of the contours on the plan can be made. When the contours have been

located, the cross-section lines and elevations are erased unless the plan is intended to be used as a working drawing. As a rule all useful data, such as construction lines and dimensions, are left on a working drawing.

When the contours are located by any other means the principle is the same. The points whose elevations have been determined are plotted by scale and protractor, and the contours are interpolated between the elevations and sketched on the plan.

462. CROSS-SECTIONS. — In plotting on cross-section paper, the rulings of the paper are used as the scale, and all the dimensions of the cross-section, which are to be plotted, are laid off by counting the number of squares on the cross-section paper.

In highway, railroad, and dam construction it is often necessary to keep a record of the progress made on the earthwork by plotting the cross-section at each station, and, as the work goes on, to mark on each section in colored ink the progress of the work for each month. In this way monthly estimates can be readily made, and the cross-section sheets will also give a record of the progress of the work, each month being represented by a different colored line or by a different style of line.

Where a series of cross-sections like this are to be plotted the station number and the elevation of the finished grade are recorded just under or over the section. To avoid mistakes in numbering the sections this should be done at the time of plotting the section.

As these cross-section sheets rarely go outside the office they are usually considered in the same class with working drawings, and dimensions, such as the areas of sections or the quantities of earthwork, are usually recorded on them, together with any other data which may be of use in calculating the volumes.

463. PROFILES. — Profiles are almost always plotted on profile paper, although occasionally they are plotted on the same sheet with the plan so that the two can be readily compared.

The profile is intended to show (graphically) relative elevations. In most surveys the differences in elevation are so small in comparison with the horizontal distances that it is necessary to exaggerate the vertical scale of the profile so that the eleva-

tions can be read from the profile with a reasonable degree of accuracy. The horizontal scale of the profile should be the same as the scale of the plan, but the vertical scale should be exaggerated, say, 5 to 20 times the horizontal scale, depending upon how close it is desired to read the elevations from the drawing. If the horizontal scale of the profile is 80 ft. to an inch its vertical scale should probably be 20, 10, or 8 ft. to an inch.

464. In plotting any profile the first step is to lay it out properly on the paper, i.e., to decide, from an examination of the range of the elevations, where to start it on the paper so that it will look well when completed, and so that any additions or studies which may subsequently be drawn on it will come within the limits of the paper. Station 0 of the profile should come on one of the heavy vertical lines, and the heavy horizontal lines should represent some even elevation such as 100, 125, 150, etc.

The profile is plotted by using the rulings of the profile paper as a scale; it is drawn in pencil first and afterward inked in. It will be found, if these profile papers are carefully measured with a scale, that they are not as a rule very accurate. The rulings may be uniform, but owing to the shrinkage of the paper the divisions frequently do not scale as long as they should. In plotting a profile or section on such paper no attempt is made to use a scale; the scale of the paper is assumed to be correct and the intermediate points are plotted by estimation, which can almost always be accurately done since the rulings of the paper are quite close together.

The data for a profile of the ground generally consist of levels taken in the field at such points that the ground may be assumed to run straight between adjacent elevations. For this reason, in drawing the profile, the points where the slope of the ground changes should not be rounded off. On the other hand, however, the ground probably does not come to an actual angle at that point. The profile should be plotted therefore as a series of free-hand straight lines drawn so that the angles are not emphasized. When a profile is made from a contour map, the line should be a smooth, rather than an angular line.

465. Profiles of the surface of the ground are generally made for the purpose of studying some proposed construction

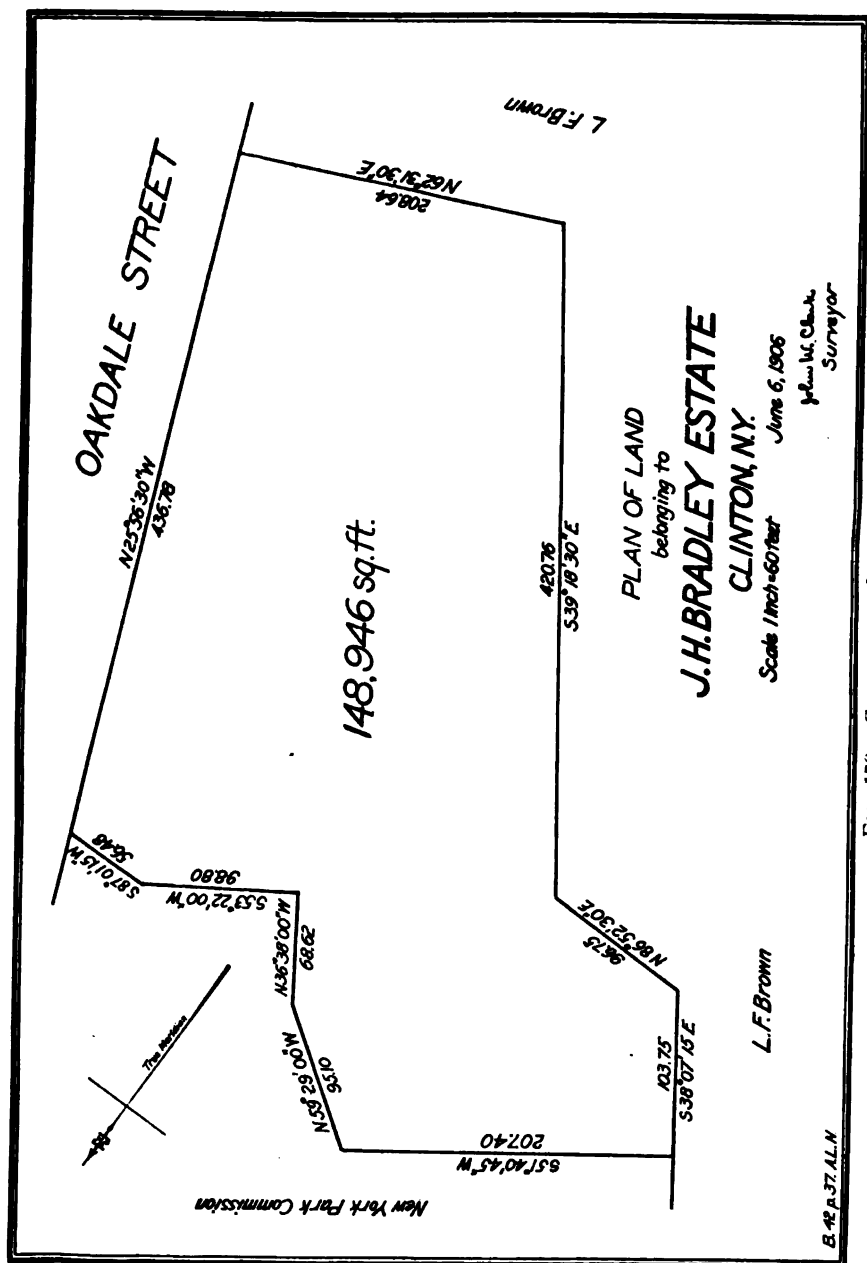

which is represented on the profile by a grade line, consisting usually of a series of straight lines. The points where the gradient changes are plotted and connected by straight ruled lines unless the proposed grade should happen to be a vertical curve (Art. 268, p. 242). Vertical lines are also drawn from the bottom of the profile to the grade line at these points.

466. When the elevations are such that the profile, if continued, will run off the top or bottom of the paper the entire surface line is lowered or raised some even number of feet, such as 20 or 50 ft., and the plotting continued: the number of feet represented between two heavy horizontal rulings of the profile paper should determine the drop or rise of the grade line. This change should be made, when convenient, on one of the heavy vertical rulings of the paper or on one of the vertical lines where the gradient changes.

467. Checks.—After plotting the surface and grade elevations in pencil, read off from the profile the station and elevation of each point as plotted and record both the station and elevation on a piece of paper. Compare these readings with the data given and make the necessary corrections. Time can be saved if one man reads off the station and elevation from the profile while a second man compares the readings with the note-book. A quick method of **plotting** profiles is to have one man read the notes while the other man plots them, but when the profile is being **checked** this method should not be used; the man, preferably the one who did not do the plotting, should **read from the profile as plotted** and these readings should be compared with the note-book.

PROBLEMS.

1. Plot the surveys given in Fig. 50, p. 100, and in Fig. 53, p. 104, by Protractor and Scale, Rectangular Coördinates, Tangents, or Chords.
2. Plot by use of Scale and Protractor the notes given in Fig. 72, p. 168, and in Fig. 116, p. 266.

CHAPTER XVI.

FINISHING AND FILING DRAWINGS.*

468. WHAT SHOULD APPEAR ON A DRAWING.— Drawings are made for a great variety of purposes, so that the data which a plan should contain depend entirely upon the use to which it is to be put. There are, however, several important things which should appear on every engineering drawing. In the first place, it should have a complete title which should be a brief description of the drawing. The title should state whether the drawing is a plan, cross-section, profile, etc.; what it represents, — a lot of land, a sewer, a railroad, etc.; the name of the owner; the place; the date; the scale; and the name of the surveyor. Besides the title, some plans, such as land plans, always require the names of owners of abutting property, and a meridian. Notes are frequently added giving such information as is necessary to interpret the plan. All essential dimensions are lettered in their proper places.

Besides these it is well to insert in some inconspicuous place (preferably near the border) the number of the note-book and the page from which the notes were plotted, and also the initials of the draftsman who made the drawing and of the man who checked it.

Fig. 179 represents a land plan which contains all of the essentials; it is a plot of the land shown in the form of notes in Fig. 52, p. 103; its computations are on p. 362; and its working plot is illustrated by Fig. 176, p. 404.

469. TRAVERSE LINES.— The convenient use of a plan sometimes requires the traverse line to be shown on the completed drawing. In such a case it is usually shown as a full colored line, each of the angle points being represented by a very small circle of the same color, the center of which marks the angle point. Sometimes the lines of the traverse are drawn to the angle points

* For methods of finishing topographic and hydrographic maps see Volume II, Chapter XI.

which are marked by very short lines bisecting the angles. Fig. 180 illustrates these two methods of marking transit points.

FIG. 180. METHODS OF MARKING ANGLE POINTS ON TRAVERSE LINES.

Triangulation stations are represented by a small equilateral triangle drawn around the station point. Fig. 115, p. 258, contains several examples of this.

470. PHYSICAL FEATURES. — The boundaries of property and the physical features which are represented on a plan, such as streets, buildings, etc., are usually drawn in black ink. Any additions or proposed changes are frequently drawn in colored ink, usually in red, although water-color is much better for the reasons stated in Art. 443, p. 395.

Shore lines and brooks are represented either in black or in Prussian blue. As a rule the shore line should be one of the heaviest, if not the heaviest line, on the drawing. Water-lining, shown in the topographical signs in Fig. 181, adds materially to the prominence and appearance of a shore line.

471. TOPOGRAPHIC CONVENTIONAL SIGNS. — On topographic maps certain physical features are shown by conventional signs which have come to be used so generally that they are practically standard throughout the country. A few of the more common of these symbols are shown in Fig. 181. The one representing "cultivated land" and the horizontal lines of the "salt marsh" and "fresh marsh" symbols are ruled; the rest are executed with an ordinary pen, Gillott's No. 303 being a good one for such work. (See also Volume II, Chapter XI.)

It will be noticed that in the symbol for "grass" the individual lines of a group all radiate from a center below the group, and also that they end on a horizontal line at the bottom. This

LEDGES — EVERGREEN TREES.

FIG. 181. TOPOGRAPHIC CONVENTIONAL SIGNS.

horizontal line, in the case of "grass" or "marsh" symbols, should always be **parallel to the bottom of the map.**

In executing "water-lining" the first line outside the shore line should be a light full line drawn just as close to the shore line as possible, and should follow very carefully every irregularity of the shore line. The next water-line should be drawn parallel to the first but with a little more space between them than was left between the shore line and the first water-line. Then the third water-line should be spaced a little farther out, and so on; five to ten lines are sufficient to represent this symbol properly. As the succession lines are added farther and farther from the shore line, the little irregularities of the shore gradually disappear until the outer water-line shows only a few irregularities opposite the most prominent ones of the shore.

Water-lining, as well as fresh marsh and salt marsh symbols, is often represented in Prussian blue. In fact, on some topographic maps most of the signs are represented by colors, — the trees by green, the grass by a light green tint, water by a light blue tint, cultivated land by yellow ochre, and so on.

Contour lines (shown in several of the cuts in Chapter X.) are almost always drawn in burnt sienna water-color. Every fifth or tenth contour is usually represented by a line slightly heavier and also a little darker in color. Gillott's No. 303 pen will be found to give good results for this work; but a contour pen, if it can be handled well, will give very uniform lines especially where the contours have no sharp turns. In numbering the contours some prefer to break the lines and place the numbers in the spaces, while others prefer to place the numbers just above or below the contours. Frequently a number is placed on every contour, but for most plans this is entirely unnecessary. If the contours are somewhat regular it is only necessary to number, say, every fifth contour. A good general rule to follow is to number only those lines which are necessary in order that the elevation of any contour may be found without appreciable mental effort. The numbers on the contours should be small plain figures in burnt sienna.

The shape of the surface of the ground is sometimes represented by hachure lines, which are illustrated in Fig. 182. The

contour lines are first sketched in pencil as a guide to the draftsman in drawing the hachure lines, which should be drawn normal to the contours. The short lines are drawn from the summit downward in rows, each row just touching the next preceding row. The steepness of the slope is represented by the weight and length of the lines,—the steeper the slope the heavier and shorter the lines. The individual lines are **equally** spaced, but on the flat slopes where the lines are lighter they have the appearance of being spaced farther apart.

and boundaries are usually represented in black ink by the symbols shown in Fig. 183.

473. LETTERING.*—The lettering on a drawing probably has more to do with its appearance than any other feature. To be able to do good lettering at first is a gift which but few men possess. It is an art that can be acquired by the most awkward draftsman, however, if he will study it carefully and devote a little time to systematic practice.

Several different styles of lettering are shown in Figs. 184 and 185. The general style to use in any given case depends on the type of drawing and on the use to which it is to be put. On plans which are to be sent from the office as completed drawings such letters as the Roman or Gothic may be appropriate. Stump writing is a style of lettering which is difficult to execute but whose appearance, when well done, is very artistic. The ornate lettering in vogue a few years ago has been superseded by simpler styles which require much less time to produce. For construction drawings, like a plan of a bridge or a conduit, for example, the Reinhardt letters are used

FIG. 186. LETTERING ON SLOPES.

* For a complete discussion and illustrations of lettering see any of the following publications: "Plain Lettering," by Professor Henry S. Jacoby, published by the Engineering News Publishing Company; "Technic of Mechanical Drafting," by Charles W. Reinhardt, published by the Engineering News Publishing Company; "Letter Plates," by Professor Charles L. Adams, Mass. Inst. of Technology, published by Professor Adams.

to a considerable extent. The title of such a plan looks well lettered in either erect or inclined Gothic.

All plans should be lettered so as to read from the bottom. Unless a draftsman exercises considerable care he will find, when the plan is completed, that some of the lettering is upside down. Fig. 186 illustrates the proper lettering of lines of various slopes.

474. Titles. — The design of the title of a plan gives the draftsman an opportunity to exercise good taste. It should be so arranged and the size of the letters so chosen that the most important part of the title strikes the eye first. In general, each line of lettering should be centered, and the spacing between the lines should be so arranged that no part will either appear crowded or seem to be floating away from the rest of the title. The general outline of the title should be pleasing to the eye. In some of the larger offices, in order to save the time of the draftsman, titles are set up in type and printed on the map.

Fig. 187 shows a set of titles which are well balanced and complete. Fig. 188 shows the style of lettering appropriate for a profile, a cross-section, or construction details.

FIG. 188. TITLES OF PROFILES.

475. Notes.—Most drawings require notes of some sort. These are usually executed with a plain letter like the Reinhardt alphabet. In Fig. 189 are a few samples the general style of which is consistent with modern practice.

*Note:—This reinforcement is 8'-0" long,
and comes directly under each track.
Leave ample room for bridge-seat.*

Note:—The datum plane used for contours and soundings on this map is "Boston City Base."

Boston City Base is 0.64 ft. below base known as "Mean Low Water at Navy Yard" which is the datum used by the U.S. Coast Survey, the U.S. Engineer's Office, and the Mass. Harbor and Land Commission.

Soundings and Contours confirmed and extended by data from map (L-476) on file with Massachusetts Harbor and Land Commission.

FIG. 189. SAMPLES OF NOTES.

476. Border Lines.—The border line of a drawing should consist of a heavy single line or double lines closely spaced. It should neither be so heavy nor of such fancy design as to be conspicuous. Plain clear drawings are the practice of to-day, and the border line should be in keeping with the rest of the drawing. For drawings 2 ft. long, the border should be about $\frac{3}{4}$ " from the edge of the sheet: for drawings 4 ft. long, 1" to 1- $\frac{1}{4}$ " looks well. On some, particularly office drawings, the border is unnecessary and may be undesirable. Fig. 190 gives a few examples of simple practical border lines.

FIG. 190. BORDER LINES.

477. Meridians.—On all land plans it is customary to draw either the true or the magnetic meridian; often both of them are represented. To be in keeping with the rest of the drawing this should be simple in design. Too frequently, however, the draftsman attempts to "lay himself out" on the needle with the result that it is so large and ornate that it is the first thing in the drawing that strikes the eye. The simple meridians shown in Fig. 191 are suggested as suitable for ordinary land plans.

The plan should always be drawn, if possible, so that the

meridian will point, in general, toward the top of the drawing rather than toward the bottom. Sometimes it is drawn with its upper part above and its tail below the drawing. In such a case

FIG. 191. MERIDIANS.

the line of the meridian must never cut any of the lines of the drawings: it should be interrupted far enough from the drawing so that it cannot be mistaken for one of the property lines.

478. Scales. — On account of the shrinkage of drawing paper the scale is sometimes drawn on the plan itself **at the time that the drawing is plotted**. It is well to have it sufficiently long, say, 3 to 10 inches (depending upon the size of the drawing), so that it will be of use in detecting the amount of shrinkage. This, of course, will determine the shrinkage only in the direction of the scale. These scales are usually placed directly under the title or in one of the lower corners. Fig. 192 gives two examples of scales.

In plotting a coördinate survey, the intersections of the north and south with the east and west lines should be marked on the finished drawing, as these are of great assistance in plotting additions. Moreover the distances between these points give a reliable measure of the change in scale of the map due to shrinkage.

479. SHRINKAGE OF DRAWING PAPERS. — All of the papers in use will shrink and swell more or less with variations of

weather conditions. The heavy mounted papers are affected the least, but large drawings even on such paper will be found on examination to change in size perceptibly. The fact that they do not always shrink the same amount in different directions

FIG. 192. SCALES.

makes it difficult to estimate the amount of the change and to allow for it. This effect can be estimated quite closely, however, by testing the drawing by measuring accurately a few lines running in different directions **when it is plotted** and scaling the same lines at any other time and making allowance for the change. Scaled distances on tracing cloth are quite unreliable if it is not kept in a dry place, and blue-prints generally shrink in washing so that scale measurements taken from them usually contain considerable error.

480. MAPS OF LARGE EXTENT. — Some maps, like the location map of a railroad or the map of a city, are so large that they must be made in sections. In such cases two slightly different methods are employed. One method is to plot the several sheets so that the drawing on one will extend to but not include any of the drawing on the adjacent sheet, the limits of the drawings being defined by straight lines. The other method is to have the drawing on each sheet lap over the drawings on the adjacent sheets a little. In this case marks are made on all drawings which make it possible to fit them to the corresponding marks on the adjacent drawings when they are being used jointly.

In attempting to arrange the sheets of adjacent drawings after they have been in use for any considerable time, it is often found that they do not fit well on account of the unequal shrinking and

swelling of the paper. Moreover in plotting lines on separate sheets so that they will fit exactly, there are mechanical difficulties which can only be appreciated by the draftsman who has had experience with them. These objections, together with the fact that a comprehensive view of the whole situation cannot be taken in at one time, have led some engineers to prefer large and unwieldy drawings to a system of separate sheets, but the latter are much more convenient when the plans are to be used in the field.

481. INKING IN A PROFILE. — The surface line is usually shown as a full firm black line and the grade line as a full red line (Art. 443, p. 395). A horizontal base-line is sometimes drawn in red a short distance above the bottom of the paper and vertical red lines are drawn from this line to the grade line at every change of gradient and at both ends of the profile. On these vertical lines are recorded the grade elevations at these points and the "plus" if the place where the gradient changes is not at a full station. On the base-line between these red vertical lines is recorded the gradient of the grade line above. Under the base-line is the stationing, which is marked at every heavy vertical ruling of the profile paper, together with any other notes of alignment which may be desired.

Information such as the names of streets, brooks, etc., is lettered vertically above the profile and at the proper station. A title and the scale are sometimes placed on the face of the profile; sometimes these are put on the back of the profile at one end of it (or both in the case of a long profile), so that the title can be read when it is rolled up.

482. CLEANING DRAWINGS. — Every drawing, during its construction, collects more or less dirt. Often construction lines are drawn which must be erased when the plan is completed. In cleaning a drawing an ordinary soft pencil eraser is used for the pencil lines while a sponge eraser or stale bread crumbs will remove the dirt satisfactorily without affecting the ink lines.

To take off the pencil lines and dirt from tracing cloth, wash the drawing with a cloth saturated with gasoline or benzine. This will remove pencil lines entirely and will clean

the tracing perfectly without any injurious effect on the tracing cloth.

483. FILING DRAWINGS. — While the particular method of filing plans varies considerably in different offices, there are a few general ideas carried out by all drafting offices in regard to the preservation as well as the systematic filing of drawings. There is no doubt that the best method of filing plans is to keep them flat, but this is not practicable with large plans which must usually be filed in rolls. In all systems of plan filing there appears to be a proper use of both flat and rolled plans.

In large offices plans are, as a rule, made in several standard sizes prescribed by the rules of the office, and are filed flat in shallow drawers which are built to fit the different sizes of drawings. In some offices the adherence to standard sizes is very rigid, and considerable time is often spent to bring drawings within the limits of one of these sizes. When these sizes are exceeded the plans are either made in sections of standard size, as explained in Art. 480, or they are made as large plans which are rolled and filed away in pasteboard tubes. Sometimes very large plans are filed flat by hanging them from an overhead frame.

Plans filed flat are marked each with its proper index number in one corner, preferably the lower right-hand corner, so that as the drawer is opened the numbers can be readily examined. In some offices it is required that in returning a drawing it shall be placed in its proper order in the drawer as well as in the proper drawer, while in other offices the plan drawers are made very shallow, so as to contain only about 15 or 20 drawings, and when a plan is returned no attempt is made to put it in any particular place in the drawer, there being, at the most, only a very few drawings to handle to obtain the one desired.

Rolled drawings are marked on the side of the rolls at each end so as to be easily read by one standing in front of the shelf on which the plans are stored. Another style of roll is closed at one end with a white label on the outside of the closed end. When the plan has been put into the tube it is so placed on the

shelf that the label on which the plan number is marked is at the front edge of the shelf where it can be conveniently read. When the plan is in use the empty tube is left on the shelf with its open end outward so that its number is in the back part of the shelf where it cannot be read.

Large plans which are made in sections are often filed in large folios or books in such a way that they can be readily taken out and used separately.

484. INDEXING DRAWINGS. — There are so many systems of indexing plans that no attempt will be made to explain them other than to suggest a few of the essentials of any good system. Every system of numbering the plans should be such that one can tell from its number whether the drawing is a sketch, a working drawing, a finished drawing, a tracing, or a process print. The numbering also should suggest the type of drawing, as a land plan, a construction plan, etc.

For offices where few plans are on file an index book may suffice for recording the plans, but in large drafting offices the card catalogue system is used extensively. By a judicious use of "markers" a card catalogue system can be so devised that it will be necessary to examine only a very few cards to find the one corresponding to any plan. Frequently it is necessary to index a plan by two or three different cards under different general headings.

485. FILING NOTE-BOOKS. — Note-books should always be filed in vaults where they will be protected against fire. Too frequently through lack of forethought note-books containing information which it has cost thousands of dollars to collect are carelessly filed on a shelf in the drafting office. In some offices the rules require that every note-book and valuable plan shall be placed in the vault at the end of the day's work, and this appears to be the proper practice.

Some offices go so far as to require that all notes shall be copied in ink and the original notes kept permanently filed in the vault to guard against their loss. Whether a copy is made or not, the **original** should be preserved as it has a value, in a lawsuit for instance, which any **copy** does not possess. When copies are made of the original notes they are sometimes made

in a loose-leaf book so that if any notes are taken from the office it is not necessary to take more than a very few leaves of the copy; the original notes never go from the office except in rare cases.

486. Indexing Notes. — The notes contained in the field notebooks are often indexed either in a book for this purpose or by means of a card catalogue. The method of indexing is similar to that used for plans.

487. Other Records. — Other records, such as borings, soundings, estimates, computations, etc., are carefully filed and indexed so that it will be easy to refer to them.

RIGHT TRIANGLE

OBLIQUE TRIANGLE

SOLUTION OF RIGHT TRIANGLES.

$$\sin A = \frac{a}{c} = \cos B$$

$$\cos A = \frac{b}{c} = \sin B$$

$$\tan A = \frac{a}{b} = \cot B$$

$$\cot A = \frac{b}{a} = \tan B$$

$$\sec A = \frac{c}{b} = \operatorname{cosec} B$$

$$\operatorname{cosec} A = \frac{c}{a} = \sec B$$

$$\operatorname{vers} A = \frac{c-b}{c} = \frac{d}{c}$$

$$\operatorname{exsec} A = \frac{e}{c}$$

$$a = c \sin A = b \tan A = c \cos B = b \cot B = \sqrt{(c+b)(c-b)}$$

$$b = c \cos A = a \cot A = c \sin B = a \tan B = \sqrt{(c+a)(c-a)} = c - c \operatorname{vers} A$$

$$d = c \operatorname{vers} A$$

$$e = c \operatorname{exsec} A$$

$$c = \frac{a}{\cos B} = \frac{b}{\sin B} = \frac{a}{\sin A} = \frac{b}{\cos A} = \frac{d}{\operatorname{vers} A} = \frac{e}{\operatorname{exsec} A} = b + b \operatorname{exsec} A$$

SOLUTION OF OBLIQUE TRIANGLES.

Given.	Sought.	Formulas.
A, B, a	b, c	$b = \frac{a}{\sin A} \cdot \sin B, \quad c = \frac{a}{\sin A} \sin(A+B)$
A, a, b	B, c	$\sin B = \frac{\sin A}{a} \cdot b, \quad c = \frac{a}{\sin A} \cdot \sin C.$
C, a, b	$A-B$	$\tan \frac{1}{2}(A-B) = \frac{a-b}{a+b} \tan \frac{1}{2}(A+B)$
a, b, c	A	If $\frac{1}{2}(a+b+c), \sin \frac{1}{2}A = \sqrt{\frac{(s-b)(s-c)}{bc}}$ $A = \sqrt{\frac{s(s-a)}{bc}}; \tan \frac{1}{2}A = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}}$ $\sin A = \frac{2\sqrt{s(s-a)(s-b)(s-c)}}{bc};$ $\operatorname{vers} A = \frac{2(s-b)(s-c)}{bc}$
	area	$\text{area} = \sqrt{s(s-a)(s-b)(s-c)}$
A, B, C, a	area	$\text{area} = \frac{a^2 \sin B \cdot \sin C}{2 \sin A}$
C, a, b	area	$\text{area} = \frac{1}{2} a b \sin C.$

TABLE VIII. TRIGONOMETRIC AND MISCELLANEOUS FORMULAS.

GENERAL TRIGONOMETRIC FORMULAS.

$$\sin A = 2 \sin \frac{1}{2} A \cos \frac{1}{2} A = \sqrt{1 - \cos^2 A} = \tan A \cos A = \sqrt{\frac{1}{2}(1 - \cos 2A)}$$

$$\cos A = 2 \cos^2 \frac{1}{2} A - 1 = 1 - 2 \sin^2 \frac{1}{2} A = \cos^2 \frac{1}{2} A - \sin^2 \frac{1}{2} A = 1 - \text{vers } A$$

$$\tan A = \frac{\sin A}{\cos A} = \frac{\sqrt{1 - \cos^2 A}}{\cos A} = \frac{\sin 2A}{1 + \cos 2A}$$

$$\cot A = \frac{\cos A}{\sin A} = \frac{\sin 2A}{1 - \cos 2A} = \frac{\sin 2A}{\text{vers } 2A}$$

$$\text{vers } A = 1 - \cos A = \sin A \tan \frac{1}{2} A = 2 \sin^2 \frac{1}{2} A$$

$$\text{exsec } A = \sec A - 1 = \tan A \tan \frac{1}{2} A = \frac{\text{vers } A}{\cos A}$$

$$\sin 2A = 2 \sin A \cos A$$

$$\cos 2A = 2 \cos^2 A - 1 = \cos^2 A - \sin^2 A = 1 - 2 \sin^2 A$$

$$\tan 2A = \frac{2 \tan A}{1 - \tan^2 A}$$

$$\cot 2A = \frac{\cot^2 A - 1}{2 \cot A}$$

$$\text{vers } 2A = 2 \sin^2 A = 2 \sin A \cos A \tan A$$

$$\text{exsec } 2A = \frac{2 \tan^2 A}{1 - \tan^2 A}$$

$$\sin^2 A + \cos^2 A = 1$$

$$\sin (A \pm B) = \sin A \cos B \pm \sin B \cos A$$

$$\cos (A \pm B) = \cos A \cos B \mp \sin A \sin B$$

$$\sin A + \sin B = 2 \sin \frac{1}{2} (A + B) \cos \frac{1}{2} (A - B)$$

$$\sin A - \sin B = 2 \cos \frac{1}{2} (A + B) \sin \frac{1}{2} (A - B)$$

$$\cos A + \cos B = 2 \cos \frac{1}{2} (A + B) \cos \frac{1}{2} (A - B)$$

$$\cos B - \cos A = 2 \sin \frac{1}{2} (A + B) \sin \frac{1}{2} (A - B)$$

$$\sin^2 A - \sin^2 B = \cos^2 B - \cos^2 A = \sin (A + B) \sin (A - B)$$

$$\cos^2 A - \sin^2 B = \cos (A + B) \cos (A - B)$$

$$\tan A + \tan B = \frac{\sin (A + B)}{\cos A \cos B}$$

$$\tan A - \tan B = \frac{\sin (A - B)}{\cos A \cos B}$$

TABLE IX. CIRCULAR CURVE FORMULAS

R = Radius	M = Middle Ordinate
I = Central Angle	L_s = Length of Arc
T = Tangent Distance	C = Chord
E = External Distance	t = Tangent Offset
<hr/>	
$T = R \tan \frac{1}{2} I$	$L_s - C = \frac{C^2}{24R^2}$ (Approximate)
$E = R \operatorname{exsec} \frac{1}{2} I$	$M = R - \sqrt{R^2 - \left(\frac{C}{2}\right)^2}$
$M = R \operatorname{vers} \frac{1}{2} I$	$M = \frac{C^2}{8R}$ (Approximate)
$C = 2R \sin \frac{1}{2} I$	$t = \frac{C^2}{2R}$
$L_s = R \times \text{Circular Measure } I$	

TABLE X. GEOMETRIC FORMULAS.

Required.	Given.	Formulas.
Area of		
Circle	Radius = r	πr^2
Sector of Circle	Radius = r , Arc = L_s	$\frac{r L_s}{2}$
Segment of Circle	Chord = C , Middle Ordinate = M	$\frac{2}{3} C M$ (Approximate)
Ellipse	Semi-axes = a and b	πab
Surface of		
Cone	Radius of Base = r ; Slant Height = s	$\pi r s$
Cylinder	Radius = r , Height = h	$2 \pi r h$
Sphere	Radius = r	$4 \pi r^2$
Zone	Radius of Sphere = r , Height of Zone = h	$2 \pi r h$
Volume of		
Prism or Cylinder	Area of Base = b ; Height = h	$b h$
Pyramid or Cone	Area of Base = b ; Height = h	$\frac{b h}{3}$
Frustum of Pyramid or Cone	Area of bases = b and b' ; Height = h	$\frac{h}{3} (b + b' + \sqrt{bb'})$
Sphere	Radius = r	$\frac{4}{3} \pi r^3$

TABLE XI. LINEAR MEASURE.

1 foot = 12 inches
 1 yard = 3 feet
 1 rod = $5\frac{1}{2}$ yards = 16 $\frac{1}{2}$ feet
 1 mile = 320 rods = 1760 yards = 5280 feet

TABLE XII. SQUARE MEASURE.

1 sq. foot = 144 sq. inches
 1 sq. yard = 9 sq. feet = 1296 sq. inches
 1 sq. rod = $30\frac{1}{4}$ sq. yards = 272 $\frac{1}{4}$ sq. feet
 1 acre = 160 sq. rods = 4840 sq. yards = 43,560 sq. feet
 1 sq. mile = 640 acres = 102,400 sq. rods = 27,878,400 sq. feet

TABLE XIII. LINEAR MEASURE—METRIC SYSTEM.

1 myriameter = 10 kilometers
 1 kilometer = 10 hectometers
 1 hectometer = 10 decameters
 1 decameter = 10 meters
 1 meter = 10 decimeters
 1 decimeter = 10 centimeters
 1 centimeter = 10 millimeters

TABLE XIV. SQUARE MEASURE—METRIC SYSTEM.

1 centare = 1 sq. meter
 1 are = 100 sq. meters
 1 hectare = 100 ares = 10,000 sq. meters

TABLE XV. CONSTANTS.

	Number.	Logarithm.
Ratio of circumference to diameter	3.14159	0.49715
Base of hyperbolic logarithms	2.71828	0.43429
Modulus of common system of logs	0.43429	9.63778-10
Length of seconds pendulum at N. Y. (inches)	39.1017	1.59220
Acceleration due to gravity at N. Y.	32.15949	1.50731
Cubic inches in 1 U. S. gallon	231	2.36361
Cubic feet in 1 U. S. gallon	0.1337	9.12613-10
U. S. gallons in 1 cubic foot	7.4805	0.87393
Pounds of water in 1 cubic foot	62.5	1.79588
Pounds of water in 1 U. S. gallon	8.355	0.92195
Pounds per square inch due to 1 atmosphere	14.7	1.16732
Pounds per square inch due to 1 foot head of water	0.434	9.63749-10
Feet of head for pressure of 1 pound per square inch	2.304	0.36248
Inches in 1 centimeter	0.3937	9.59517-10
Centimeters in 1 inch	2.5400	0.40483
Feet in 1 meter	3.2808	0.51598
Meters in 1 foot	0.3048	9.48402-10
Miles in 1 kilometer	0.62137	9.79335-10
Kilometers in 1 mile	1.60935	0.20665
Square inches in 1 square centimeter	0.1550	9.19033-10
Square centimeters in 1 square inch	6.4520	0.80969
Square feet in 1 square meter	10.764	1.03197
Square meters in 1 square foot	0.09290	8.96802-10
Cubic feet in 1 cubic meter	35.3156	1.54797
Pounds (av.) in 1 kilogram	2.2046	0.34333
Kilograms in 1 pound (av.)	0.4536	9.65667-10
Ft.-lbs. in 1 kilogram-meter	7.23308	0.85932

APPROXIMATE VALUES OF SINES.

$$\text{Natural sine of } 1^\circ = \frac{1.75 \text{ ft.}}{100 \text{ ft.}} = \frac{1}{60} \text{ (roughly)}$$

$$\text{Natural sine of } 0^\circ 1' = \frac{0.03 \text{ ft.}}{100 \text{ ft.}}$$

$$\text{Natural sine of } 0^\circ 00' 01'' = \frac{0.3 \text{ inch}}{1 \text{ mile}}$$

APPENDICES

APPENDIX A.

PRINCIPLES OF THE STADIA.*

488. DEFINITIONS. — The *Stadia Method* is adapted to measuring distances with great rapidity and with an accuracy which is quite sufficient for many purposes. This is especially true for mapping topographic details. While the precision obtained in very careful chaining is not to be expected from stadia measurements, yet in extremely rough country, where chaining is very difficult, the accuracy of the results obtained by stadia is comparable with that obtained by direct tape measurements; furthermore, it has been found by actual tests in measuring very long lines (such as state boundaries) with the tape and checking the measurements by means of the stadia that, since the errors of stadia measurements are *compensating*, the final results obtained by the latter method have sometimes proved to be more accurate than those obtained by direct tape measurements. (See Art. 23, p. 14.)

489. INSTRUMENTS. — A transit intended for stadia work is provided with two additional horizontal hairs usually fastened to the same diaphragm as the ordinary cross-hairs and placed at a known distance apart. The distance between these two extra hairs is almost always fixed, but in some transits the diaphragm is so arranged that the distance can be adjusted. In some other instruments the stadia hairs are placed on a separate diaphragm, so that when the eyepiece is focused on the regular cross-hairs the stadia hairs are invisible and vice versa; these are called *disappearing stadia hairs*. The instrument is also provided with a vertical circle or arc for measuring vertical angles, since the telescope is seldom level when stadia measurements are taken.

STADIA RODS are made of a great many designs, but the accepted practice is to use rods graduated into feet and tenths, plainly painted so that they can be read at long distances. The hundredths of a foot are usually estimated.

* For a more detailed treatment of this subject see Volume II, Chapter IV.

490. FUNDAMENTAL PRINCIPLES. — If the telescope is sighted at a graduated (vertical) rod, a certain space on the rod will be intercepted between the stadia hairs, this interval depending upon the distance of the rod from the instrument, so that this space intercepted on the rod is the measure of the distance from the rod to the instrument. In Fig. 193 let L be the optical center of the objective, * a and b the stadia hairs, A and B the points on the rod where the stadia hairs appear to cut it. AB is then the intercepted space when the rod is at the distance LX . If the rod were moved to the position Y , where the distance LY is half LX , then the intercepted space $A''B''$ would be half AB . The first

FIG. 193.

principle involved then is simply that of proportional sides of similar triangles.

Let $Lp = f_1$, and $LX = f_2$ (these distances being known as *conjugate foci*); also let $AB = s$, and $ab = i$; then

$$f_2 : f_1 = s : i \quad (1)$$

When the rod is moved from X to Y it becomes necessary to alter the focus of the telescope, i.e. the distance between the objective and the stadia hairs is increased, the new position of the stadia hairs being at a' and b' . This changes the angle from aLb to $a'Lb'$, so that the points on the rod now covered by the stadia hairs are not A'' and B'' but are A' and B' . Lines AA' and BB' continued

* While it is not theoretically exact to draw the lines Aa and Bb straight through the optical center it is customary to use this simple construction, and no appreciable error is introduced either in the results or in the theory used in reaching these results.

will meet at a point V , in front of the objective. If a third position of the rod be taken between X and Y , and lines drawn through A and B in the same way as AA' and BB' were drawn, these lines will cut LX in the same point, V , already found. To determine the position of this point, to which all of the stadia distances refer, we make use of the "Law of Lenses" which is expressed by the equation (demonstrated in treatises on Physics)

$$\frac{1}{f_1} + \frac{1}{f_2} = \frac{1}{F} \quad (2)$$

where F is the focal length of the objective, i.e. the distance from L to the cross-hairs when the objective is focused for an infinite distance (Art. 46, p. 35). Solving equations (1) and (2) simultaneously for f_2 we obtain

$$f_2 = \frac{F}{i} s + F.$$

This shows that the distance LX is made up of the variable distance VX , or $\frac{F}{i}s$, and the constant LV , or F . Hence all the stadia distances, as determined by direct proportion, refer to a point V in front of the lens at a distance equal to the focal length of the objective. Since it is the distance from the rod to the center of the instrument which is desired it is necessary to add to LX the distance LC , which is the distance between the objective and the center of the instrument; calling this c , the complete expression is then

$$\text{Distance} = \frac{F}{i} s + (F + c) \quad (3)$$

491. Stadia Constants. — The ratio $\frac{F}{i}$ is constant for any instrument in which the stadia hairs are not adjustable, and is generally made equal to $\frac{100}{1}$ so that if the interval AB (Fig. 193) is 1 foot the distance VX will be 100 feet, or, in other words, every hundredth of a foot on the rod corresponds to 1 foot of distance from the point V .

The quantity $(F + c)$ is practically constant for any given instrument, the small variation in c (less than 0.1 ft. for a transit)

due to focusing being much smaller than the errors in the readings themselves.

The constant $\frac{F}{i}$ may be found experimentally by reading the interval on a rod held at two widely different distances (say 100 ft. and 500 ft.) which have been accurately determined by means of a tape. If the known distance and the corresponding interval on the rod are substituted in equation (3), then for each distance we will have an equation; the simultaneous solution of these will give the value of $\frac{F}{i}$.

The constant $(F + c)$ may be found accurately enough for all ordinary purposes by direct measurement. The distance between the objective and the stadia hairs when the telescope is focused on a distant object equals the focal length F . The distance c may be taken as the distance between the objective and the center of the instrument when focused for an average sight. As it is generally not customary to read stadia distances closer than about 1 foot it is sufficient to regard $(F + c)$ as 1 foot for all ordinary transits, although it may actually vary from 0.75 to 1.25 ft. In work where a distance of one or two feet becomes of no importance the constant $(F + c)$ may be neglected.

FIG. 194.

492. FORMULAS FOR INCLINED SIGHTS.—In the preceding discussion the rod is supposed to be held perpendicular to

the line of sight. In taking measurements on sloping ground it is customary to hold the rod *plumb*, regardless of the slope, since it is not as easy to judge when the rod is perpendicular to the line of sight as to estimate when it is held *plumb*.

Since the rod is not held perpendicular to the line of sight the vertical and horizontal distances cannot be computed from a simple right triangle. In Fig. 194 let AB be the intercept on the rod when held *plumb*, and $A'B'$ the intercept if the rod were held perpendicular to the line of sight, i.e. $A'B'$ is perpendicular to CO . In the triangles $AA'O$ and $BB'O$ the angles A' and B' differ from 90° by the angle m , which is usually about $0^\circ 17'$. It is customary to solve these two triangles as right triangles; a comparison with the exact solution shows that the resulting error is always negligible.

$$\text{Hence} \quad A'B' = AB \cos \alpha \text{ (nearly).}$$

$$\begin{aligned} \text{But} \quad CO &= \frac{F}{i} A'B' + (F + c) \\ &= \frac{F}{i} AB \cos \alpha + (F + c). \end{aligned}$$

$$\begin{aligned} \text{The Horizontal Distance} &= CD = CO \cos \alpha \\ &= \frac{F}{i} AB \cos^2 \alpha + (F + c) \cos \alpha \quad (4) \end{aligned}$$

$$\begin{aligned} \text{The Vertical Height} &= DO = CO \sin \alpha \\ &= \frac{F}{i} AB \cos \alpha \sin \alpha + (F + c) \sin \alpha \\ &= \frac{F}{i} \times \frac{AB}{2} \sin 2\alpha + (F + c) \sin \alpha \quad (5) \end{aligned}$$

Equations (4) and (5) are solved in practice by three different means — by table, by diagram, and by the stadia slide rule. The slide rule is the most rapid of these and is accurate enough for ordinary purposes. In its construction it differs from the ordinary

slide rule in having certain scales based upon the first terms of formulas (4) and (5). The method of operating this rule is similar to that explained for the ordinary slide rule in Art. 359, p. 330.

493. Stadia Tables. — The Stadia Tables, p. 516, are in two parts, the upper table is for obtaining vertical heights and the lower one is for horizontal distances. The Table of Vertical Heights contains the value of the first term of formula (5) for different values of the vertical angle α when $\frac{F}{i} = 100$, and AB is 1 ft. The vertical height for any other rod interval is found by multiplying the tabular number by the space intercepted on the rod. To be mathematically exact the last term of equation (5) should be computed separately and added to the results obtained from the table; but for angles ordinarily occurring in this work, the term $\frac{1}{2} \sin 2\alpha$ is approximately equal to $\sin \alpha$, so that it is almost always sufficiently accurate to regard $(F + c)$ as part of the variable distance. For example, if the intercepted space is 2.73 we would then multiply the tabular number by 2.74, the 1 ft. constant $(F + c)$, being equivalent to 0.01 ft. interval on the rod. The only case where this is not sufficiently accurate is when the vertical angle is extremely large.

The Table of Horizontal Corrections contains the number of feet to be subtracted from the distance read, and is given in this table for different distances and for different values of α . This correction is simply the difference between the first terms of formulas (3) and (4) when $\frac{F}{i} = 100$, and is equal to $AB \sin^2 \alpha$, since AB in formula (4) is the same as s in formula (3). The second terms of equations (3) and (4) are practically equal for the angles usually occurring in this work, hence it is customary to add to the measured distance the constant 1 ft. and then to apply the horizontal correction from the table. Examples illustrating the use of these tables are given in Art. 495.

494. Fieldwork. — The horizontal angles are usually recorded as azimuths; the method of determining these is described in Art. 144, p. 108. A rough check on the azimuths may be obtained by reading the bearings of all important lines. If the survey is connected with triangulation or if special observations have been

made so that the true azimuth of some line is known, then all azimuths are referred to the true meridian. If the true meridian has not been determined the magnetic meridian may be used, or any arbitrary line may be chosen as the line of reference.

The transit points may be located by a traverse run with a transit and tape or by the transit and stadia, according to the accuracy desired. Whether the distances are found by tape or by stadia it is well to check them by stadia readings, forward and backward. From each transit point "side shots" are taken to as many points as are needed for locating topographic details. The distances are read by setting the lower stadia hair on a whole foot-mark on the rod and counting the feet and tenths, and estimating the hundredths, in the intercepted space. Care should be taken that the middle horizontal hair is not read by mistake in reading the distance. If, however, a sight is so long that the rod does not reach from one stadia hair to the other the distance may be obtained with a fair degree of accuracy by reading first the space between the upper and the middle hairs and then, after resetting, the space between the middle and the lower hairs, and adding the two results.

If elevations are to be determined the process is to sight the middle hair on a point on the rod as far above the bottom as the center of the transit is above the ground at the instrument, and then to read the corresponding vertical angle. The distance from the ground to the center of the instrument at the transit point may be conveniently measured with a pocket tape and is usually recorded in the notes as the "H. I."; this must not be confused with the H.I. used in leveling. The slope thus determined by the vertical angle is the same as the slope between the two points on the ground.

In order to economize time the vertical hair should first be set on the rod, then the distance read; the middle horizontal hair is next set on the "H.I."; the transitman is then through with the settings and should direct the rodman to proceed to the next point. In the meantime, the transitman can read the azimuth and the vertical angle.

495. Notes. — There are various arrangements of stadia notes depending upon the details of the fieldwork and upon individual

tastes. Fig. 195 shows the left-hand page of a form of notes which is in common use. The right-hand page of the notes is reserved for the sketch and general descriptions. Numbers corresponding to the points in the first column are marked on the sketch in their proper location.

By referring to these notes it will be seen that the transit points are distinguished from the other points by the usual symbol for stadia stations, consisting of a square with a dot in the middle. The transit is set up at Station 1, the vernier set at 0° , and then sighted in the direction of the magnetic South and the lower plate clamped. Then the distance from the ground to the center of the instrument is measured and recorded as H.I. = 4.23. A sight is then taken on the bench mark, which is point 1; its elevation in this case is such that a rod-reading of 7.61 is obtained with the telescope

Survey of Cedar Brook, Canton. White & Nelson Oct. 17, 1906.						
Pt.	Dist.	Az.	Bear.	Vt. Ang.	Diff. El.	Elev.
Transit 1, <i>O on Magnetic S.</i>			H.I. = 4.23			84.61
1 B.M.	62	$87^\circ 15'$		$0^\circ 00'$ on 7.61		81.23
2	98	$93^\circ 10'$		$+0^\circ 50'$		
3	127	$86^\circ 20'$		$+1^\circ 32'$		
4	176	$85^\circ 30'$		$+4^\circ 17'$		
2	205	$92^\circ 16'$	$N 87^\circ W$	$+8^\circ 12'$		
Transit 2, <i>B.S. on 1, H.I. = 4.61</i>						
1	206	$272^\circ 16'$		$-8^\circ 13'$		
5	74	$73^\circ 10'$		$+2^\circ 15'$ on 8.6		
6	213	$105^\circ 40'$		$+6^\circ 55'$		

FIG. 195.

leveled. From the elevation of the B.M. (81.23), the elevation of the ground at the transit point (84.61) is computed and entered in the notes. Whenever elevations are desired either level readings or vertical angles are recorded, to the nearest minute, in the column marked "Vt. Ang." For example, opposite point 2 a vertical angle of $+0^\circ 50'$ is taken with the center cross-hair sighted on 4.23 (the H.I.) on the rod; where it is not possible to

sight on the H.I., as at point 5, the sight is taken on some whole number of feet above or below the H.I., as in this case, on 8.61.

The last two columns are not as a rule computed in the field. They are sometimes calculated by use of tables. As an illustration of the use of Table XVI the difference in elevation opposite point 2 may be found as follows. In Table XVI, in the column headed 0° and opposite 50' is found 1.45 as the difference in elevation; this is multiplied by 0.98, which gives 1.42 as the quantity to introduce in the column marked "Diff. El.," which is the difference in elevation between the ground at the instrument and at point 2. The elevation of point 2, to the nearest tenth, is $84.6 + 1.4 = 86.0$, and this is put in the last column opposite point 2. Similarly the calculation for point 5 gives $3.93 \times 0.74 = 2.9$. But the sight was taken 4 ft. above the H.I., therefore the Diff. El. = -1.1. The elevation of \square 2 is determined from \square 1 the same as any other point and the elevation of point 5 is computed from the elevation of \square 2. The ordinary slide rule used in connection with these tables furnishes a rapid means of making these calculations.

In computing the elevation of one instrument point from another it is well to carry the difference in elevations to hundredths of a foot, but for side shots it is sufficient to carry it to tenths only, since the elevation of no other point is affected. More accurate results can be obtained if the rod is held on top of the stake at the transit points instead of on the ground, and the H.I. measured from the top of the stake.

To obtain the horizontal distance between two points, say \square 1 and \square 2, we make use of the Table of Horizontal Corrections; for a distance of 205 and an angle of $8^\circ 12'$ we find that the correction to be subtracted is about 4 ft. Assuming that the constant ($F + c$) has not yet been added, we have for the true horizontal distance $205 + 1 - 4 = 202$ ft.

APPENDIX B.

THE PLANIMETER.

The planimeter is an instrument used to determine the area of a figure by moving the tracing point of the instrument around the perimeter of the plotted area. When the figure has a regular shape its area can be easily computed from its dimensions, but when the boundaries are crooked, such as river boundaries, the planimeter is most useful, and with careful manipulation results can be obtained which are accurate enough for many engineering purposes.

The Amsler Polar Planimeter. — The most common planimeter is the *Amsler Polar Planimeter* (Fig. 196). This instrument

FIG. 196.

has two arms, BO and HP . The arm BO is of fixed length; it is anchored at O by a needle point which sticks into the paper and is held in position by a small weight which is detachable. At B it is connected by a pivot to a collar, C , through which the tracing arm HP can slide. At P is a tracing point which is moved along the outline of the area to be measured; the distance CP being adjusted to conform to the scale of the map. The graduated wheel S , whose axis is parallel to HP , records the area in units dependent upon the length of the arm CP .

The planimeter rests then on three points, the anchor, the tracing point, and the periphery of the wheel. As the tracing point is moved around the given area, the wheel drags along, sometimes slipping and sometimes rolling, and the difference between the reading of the scale on the wheel at the beginning and end of the circuit represents the area of the figure. Besides the scale on the wheel there is a small disk D which records the number of full revolutions of the wheel. The result of reading the disk, the wheel, and its vernier will usually give four figures.

Since the length of the anchor arm is fixed and the point O stationary, the wheel moves on the circular arc whose center is O and whose radius (R) is the distance from O to the wheel. The readings of the scale will therefore record the length of arc between the point where it rested at the beginning and end of the circuit.

If in moving the tracing point its arm be maintained in such a position with reference to the anchor arm that the plane of the wheel will always pass through the anchor point, it is evident that the wheel will not revolve at all on its axis but will slip on the paper without changing its reading. The tracing point can therefore be started at a given point and moved about in the path of a circumference, returning to the same point again without recording any reading of the wheel. This circumference is called the *zero circumference*, or the *correction circle*.

Theory of the Amsler Polar Planimeter. — The following proof has been taken from Cours de Mécanique, by Édouard Collignon.

Let A (Fig. 197) be the area to be measured. Conceive cd (corresponding to the tracing arm) to be a straight line of constant length moving so that one end d is always upon the outline of A and the other end c is always upon a given curve cc' (in general a circle described from O).

Let cd and $c'd'$ be consecutive positions of the moving line, and let an expression be obtained for the elementary area $cd d'c'$ generated by the line in moving from the first position to the second. This movement may be considered as composed of two

of the wheel in the translation from cd to $c'e$ corresponding to the normal displacement only) + the arc $L'd\alpha$ (letting $cF = L' = c'F'$).

$$\therefore r \cdot d\theta = dh + L'd\alpha \quad [2]$$

With the wheel beyond c on dc produced, $r \cdot d\theta = dh - L'd\alpha$
Eliminating dh from equations [1] and [2]

$$dA' = r \cdot L \cdot d\theta + \left(\frac{L^2}{2} - LL' \right) d\alpha \quad [3]$$

$$\int dA' = \int r \cdot L \cdot d\theta + \int \left(\frac{L^2}{2} - LL' \right) d\alpha \quad [4]$$

Conceive now the point d to traverse the entire outline of A , the elements dA' being reckoned positively or negatively according to the direction in which they are generated. Two cases are to be noticed:

(a) When the directing curve cc' is exterior to (but not including) the area A (Fig. 197). The algebraic sum, $\int dA'$, will be the difference between the sum of the positive and the sum of the negative elementary areas, and will equal the area A .

$$\begin{aligned} \int r \cdot L \cdot d\theta &= rL\theta \\ &= Lu \quad (\text{where } u = r\theta = \text{algebraic sum of arcs} \\ &\quad \text{applied to paper by wheel}). \end{aligned}$$

$$\int d\alpha = 0, \text{ since } cd \text{ returns to its original position without having made a circuit about } O.$$

$$\therefore \text{ Integrating expression [4], } A' = A = Lu.$$

(b) When the directing curve cc' is within the area A (Fig. 198). The line cd now makes an entire revolution in order to return to its primitive position, and $\int d\alpha = 2\pi$. Also the area

$$A = \int dA' + \text{area of circle described by } Oc.$$

By integrating expression [4]

$$A' = Lu + 2\pi \left(\frac{L^2}{2} - LL' \right)$$

$$A = A' + \pi R^2$$

$$= Lu + \pi (L^2 - 2 LL' + R^2)$$

$$= Lu + \text{the area of a circle of radius } \sqrt{L^2 - 2 LL' + R^2}.$$

The sign of $2 LL'$ is $-$ if the wheel be between tracing point and pivot point; otherwise it is $+$,

FIG. 198.

This circle is called the "circle of correction" and its value may be found by measuring with the planimeter a circle or other figure of known area inclosing the directing curve cc' .

It will be seen that the radius $\sqrt{L^2 \pm 2 LL' + R^2}$ is the distance from anchor point to tracing point, when the plane of the wheel passes through the anchor point; in other words, is the radius of the zero circle.

If C = circumference of wheel

and n = number of revolutions made in a given measurement

$$Lu = LnC$$

If L and C be given in inches A will be found in square inches. By varying L the area A corresponding to one revolution of the wheel ($n = 1$) may be varied at pleasure. Commonly, if the area is sought in square inches the length L is made such, by adjustment on the tracing arm, that one complete revolution of the wheel corresponds to 10 square inches of area.

Since, for the anchor point **outside** the area to be measured, $A = LnC$, it appears that for any setting of L , A is directly proportional to n . So that L may be set at random and n' determined for a known area A' (say a circle or rectangle) in whatever unit the area is desired, then $\frac{A}{A'} = \frac{n}{n'}$. But this process evidently does not apply to the case of anchor point **inside** the area to be measured.

In finding the area of the circle of correction, the instrument gives directly only the **difference** between circle and known area.

If the known area lies entirely outside of circle (Fig. 199), then the record of instrument gives the shaded area only, and this **subtracted** from known area will equal the circle of correction.

If the known area (Fig. 199) does not lie entirely without the

FIG. 199.

circle then record of instrument must be **added** to the known area if the circle of correction is the larger, otherwise **subtracted**.

Use of Polar Planimeter. — In measuring a closed area the anchor point is pressed into the paper at a position **outside** of the area of the figure, if it is not too large, and the tracing point is started from a definite point on the periphery of the area, preferably such as will bring the two arms approximately at right

angles to each other. The wheel is then read. The tracing point is then moved around the outline of the area, being careful to follow the line accurately, until the starting point is reached again. The wheel is again read and the difference between the two wheel readings gives the area in the unit depending upon the setting of the arm. The disk should also be read when the wheel is read if the area is large enough to require a full revolution of the wheel. Care must be taken to bring the tracing point **exactly** back to the point from which it was started.

While some instruments have a tracing arm of fixed length, so that all areas recorded by the wheel are in the same unit, square inches for example, many planimeters have adjustable tracing arms which can be set by means of a clamp and slow-motion screw at whatever reading of the scale on the tracing arm is desired. Usually it will be necessary to use a reading glass to make this setting accurately. The arm is sometimes marked by vertical lines and beside these lines are letters and figures indicating the unit of area to which the setting corresponds. In some instances, however, the scale is marked as a continuous scale and the proper settings for given area units are supplied by the instrument maker.

A way of avoiding the use of the correction circle in measuring large areas is to divide the area into smaller ones by light pencil lines and to determine each fractional area separately. If, however, the anchor point is placed inside the area the value of the correction circle must be applied to the reading of the wheel as explained in the previous article.

A planimeter can be readily used even though the setting of the arm is not known. A square, say four inches on a side, can be accurately drawn on the map and its area determined with the planimeter in the usual manner, making several independent determinations with the anchor point in different positions so that if there are any irregularities in the paper over which the wheel passes which are affecting one result, this error will not enter into the other determinations. The mean of these results divided by the number of square inches in the given area will be the wheel reading for one square inch. This being determined the area in square inches of any given figure can be obtained

by the planimeter and this can be easily converted into the desired units by using the scale of the map.

It is well before beginning to trace out the figure to run the tracing point around the figure, keeping approximately on the line so as to be sure that the anchor point has been placed in a satisfactory position. To insure accuracy the area should always be measured by at least two independent determinations with a different position of the anchor for each measurement for the reason explained above. Furthermore, it is of extreme importance to check the area roughly by observation or by scaling and rough calculations. If the paper has shrunk since the drawing was made the amount of this change should be determined and allowed for in arriving at a correct value for the area. By the use of a polar planimeter a result which is not in error more than one per cent is easily obtained, except in the case of very small areas.

The Rolling Planimeter. — The rolling planimeter, unlike the polar planimeter, is not anchored to the drawing. It has a tracing point at the end of an adjustable pivoted arm which is fastened to a frame which is supported on two rollers. In using this planimeter the whole instrument moves forward or backward in a straight line while the tracing point traverses the outline of the area to be measured.

With the rolling planimeter it is possible to obtain a remarkable degree of accuracy, results correct to a tenth of a per cent being easily reached.

APPENDIX C.

MOUNTING PAPER FOR DRAWINGS.

In making a large map in which a high degree of accuracy is essential, especially if the plotting is to extend over a long period of time, it will be found advantageous to mount the paper on cloth stretched upon a drawing board. When so mounted the paper presents a better surface to work upon and is less liable to change its dimensions with changes in atmospheric conditions than mounted paper that is simply fastened by thumb tacks to the board.

The cloth, which may be ordinary bleached cotton, should be tacked to the edges (not to the top) of the board in such a way as to draw the cloth tightly and yet evenly. In order to prevent the paper, while drying, from tearing the cloth away from the tacks it will be necessary to space the tacks not more than an inch or so apart along the edges of the board. It is evident that a T-square cannot be used when the drawing is mounted in this manner; but since the T-square is not as reliable as a steel straight-edge the latter will be preferable in any case if great accuracy is desired.

After the cloth is stretched the back of the drawing paper should be moistened slightly with a sponge. This is done to prevent the paste from drying too rapidly. The paste used should be common flour paste such as is used for wall paper, properly thinned out, thoroughly mixed, and carefully strained to remove all dirt and lumps. It should be laid on evenly with a wide brush and so as to cover **all parts of the paper**. If any part is left dry it may spring up from the cloth and cannot afterward be made to lie flat. All pieces of dirt, lumps of paste, hairs from the brush, etc. should be picked off before the paper is laid on the cloth, as they will make rough spots on the surface of the paper which may afterward wear through or cause dirty spots. The pasting should be done quickly enough so that no part of the surface dries before the paper is mounted. It is well to run the brush around the edges the last thing before the paper is laid on the cloth.

After the paper has been thoroughly pasted it should be laid carefully on the cloth in the correct position. The center of the

paper should strike the cloth first, and should be placed at once in its final position as it is impossible to move the paper around on the cloth. It may require two persons to do this if the drawing paper is large, say "double-elephant" size or larger. As soon as the paper is in position it should be rubbed down to prevent any part from drying before it sticks to the cloth. In order to keep the surface clean a piece of manila paper may be laid over the drawing paper. It should be rubbed down in the center first, then radially outward and in such a way as not to crease or tear the paper. Care should be taken that the edges are kept well pressed down while the paste is drying; the edges of the paper expand so greatly while the paste is wet that they will rise up from the cloth and it will require constant attention for several minutes to keep the edges in contact with the cloth. The paper should **not** be rubbed parallel to the edges of the board as this is almost certain to crease the paper wherever it is not flat, and it is impossible, after the creases are once formed, to entirely remove them or to give the drawing a clean, smooth surface. If the paper is rubbed gently from the center outward the creasing may always be avoided. It should be remembered that while the paper is wet it will not stand hard rubbing. If it is found that the paper has dried in some places along the edges, a little paste may be introduced under the edge with a knife-blade and the paper held down until it has dried.

After the paste has dried enough to hold the paper securely it should be left for about 24 hours to dry thoroughly before plotting is begun, but it should not be left near a heating apparatus to dry. When the drawing paper is quite dry it may be found that small particles in the paste cause the paper in some places to project above the general surface. This defect may sometimes be remedied by taking a flat, hard surface (such as a glass paper weight) and pressing down heavily on the spot; this will press the object into the cloth or board without injuring the paper.

It is needless to say that the drawing board used must have a true plane surface if a good drawing surface is desired. The board should also be free from ink or paint stains; any stains on the board will be soaked up by the paste and are likely to show on the drawing paper.
